About the Editor

James Mattingly is Associate Professor of Philosophy at Georgetown University. Originally from the Silicon Valley in California, he studied Great Books at St. John's College in Annapolis, Maryland, and physics at University of California, Santa Cruz. He then returned to a study of the history and philosophy of science at Indiana University, where he received his PhD in 2002. Shortly before that, he was appointed assistant professor in the Georgetown University Department of Philosophy, where he has been ever since. His research is primarily in philosophy of science. He spends his efforts there about equally between general issues involving conceptual change in the sciences, the epistemology of science, the nature of scientific theories, scientific experiments, and scientific explanation on the one hand, and issues more

specific to philosophy of physics on the other, including quantum gravity, general relativity, black holes and singularities, gauge theories, thermodynamics, and electrodynamics. He also has research interests in early modern philosophy, the foundations of logic and mathematics, and the history of logical empiricism and other movements that attempted to come to grips with the profound conceptual reorientation made necessary by the revolutionary changes in science at the turn of the 20th century. He has written and lectured extensively on scientific theories, epistemology of science, the nature of scientific experimentation, and the foundations of physics. He is the author of *Information and Experimental Knowledge*, published in 2021 by The University of Chicago Press.

Introduction

The word “theory” has fascinating origins. In ancient Greek, the primary meaning of the word “θεωρία” (theory) seems to have been “looking at, viewing, beholding”.¹ It also referred to ambassadors sent out to observe the oracle, or, on other occasions, the Olympic games. A variation of the word, *theorem*, can refer to the results of some science or technical discipline (what we might think of as engineering), and this is the word that Euclid uses to refer to the things that he proves in the *Elements*, our first systematic geometry book. In those cases, the theorems, or the things observed using the discipline, were tightly linked to the act of showing and seeing, to making plain. Today we might refer to, say, number theory and some of the things that we discover or prove or explain using number theory as its theorems. While “theory” is often associated with abstraction, with complication, with abstruseness it is grounded in the concrete, observable, repeatable results of the crafts, mathematics, and science.

The word “theory” is also, ironically, tightly linked equally to certainty and to pure speculation. On the one hand, in the popular imagination, theory seems sometimes associated to, say, the quantum theory, or the theory of relativity, two disciplines that have achieved unprecedented accuracy and experimental confirmation in the century since they were first formulated. On the other hand, it is common to hear, in response to a claim about the origin of various species on the earth, that natural selection is *only* a theory. Generally, people who study scientific theories insist, and rightly so, that speculation ungrounded in prior disciplinary work and without strong observational support does not merit being called “theory.” Theories are generally well-supported explanatory

systems that organize the understanding of some discipline or sector of it. While novel theories are propounded in order to try to explain puzzling or novel data and are not accepted until they have themselves been tested, when used to make assertions about the world and what we can expect to see, a theory typically has already been stringently tested and found to be observationally adequate.

Why an Encyclopedia of Theory, and Why STEM?

A collection of articles about scientific theory in its various aspects seems worthwhile for a number of reasons. First and foremost our scientific theories are the vehicles of what we know where the results and understanding of various disciplines are codified so that they can be transmitted, taught to new members of the discipline, and integrated with the results of other disciplines. They are, relatedly, tools for understanding and controlling the phenomena studied in a discipline. This is enough to make the theories themselves of significant and enduring interest. But in addition to the multitude of individual theories in the various STEM disciplines, there is also the matter of theory as itself a topic worthy of study.

My own academic discipline is neither science, nor technology, nor engineering, nor mathematics. Instead, it is philosophy of science. Philosophers of science do make contributions, sometimes, to science (or technology, or engineering, or mathematics) but that is not what their main focus is. Their main focus is to understand science and related disciplines as *themselves* objects of study. They ask: How does physics relate to chemistry? What do biologists mean when they use the expression “species”? Do experiments in social science give secure knowledge? Beyond such discipline specific questions though philosophers of science are

1. H. G. Liddell & R. Scott (Eds.). (1945). *An intermediate Greek-English lexicon*. Oxford University Press.

interested in big questions about the nature of scientific inquiry, and one of the main foci of philosophy of science has long been the theories that are produced and used in the sciences. What kind of thing is a theory? Is it a collection of true remarks about some field? Is it a calculus for predicting things? Is it a vehicle for understanding the subject matter of some discipline? Or is it something else altogether? These are important concerns to philosophers. But philosophers' concerns are not always the concerns of scientists, and are rarely those of students. We are often seen as out of touch with the real, grounded, day to day understanding of things and we are seen as nit-picking to little effect. Happily, however, philosophers are not the only ones who ask and answer such questions. So too do sociologists of science, scientific practitioners themselves, engineers, mathematicians, logicians, and so on. These have joined in with philosophers to contribute to this encyclopedia. What you will find across the many entries in this encyclopedia is a broad diversity of disciplinary background, but it is a diversity that displays unity of purpose if not of method or disciplinary assumptions. These many perspectives highlight just some of the important ways of understanding theory in philosophy and the sciences and make it clear that there are a number of roads into an understanding of theory.

As noted earlier, this encyclopedia is designed to support the study of theory in itself as well as the study of specific theories. The reasons for this are many. First, the scope of the encyclopedia allows for highlighting the vast range of topics that fall under the concept and also highlight key developments of theory along with key uses in various STEM disciplines. Next, putting things together this way can help to normalize the proper sense of "theory" as it is used in the sciences, and allow for nuanced discussion of the limits and scope of the claims made in the sciences without falling into bimodal habits of excessive deference or thoughtless dismissal. The concreteness of the specific disciplines' theories and the variety of tools and techniques that arise in one and find application in another provides an interesting contrast. This contrast can help to illustrate the fruitfulness over time of feedback between study of theory and development of theory as an object of use in STEM disciplines, and transfer of innovations in theory

between disciplines. Finally, this encyclopedia, covering as it does such a range of topics displays the importance of interactions and feedback between theory as it used and theory as it is . . . well . . . theorized.

The encyclopedia is an attempt to shed some light on the nature of theories in the STEM disciplines. I have talked about reasons to focus on theory. But why focus on STEM? First, it may not seem to be a good category in some respects, either as an academic umbrella term or as a unified object of study. The classification of STEM fields under an umbrella term that joins the abstract pursuits of modern sciences like quantum theory and mathematics together with the concrete and practical practices of technological production and engineering may seem like a novelty thought up by ambitious administrators trying to figure out where best to direct institutional efforts and funding at fields that are likely to return measurable fruits. While there is some truth to that, it is almost precisely what Robert Boyle and folks like him were trying to do when they instituted the practice of modern science. Out of fractured and individualized practices and closely guarded techniques and knowledge developed in secret, Boyle attempted to produce an open society of inquiry, grounded in observation and reason, dedicated to improving human lives.

In any case, STEM is a term of current use, and moreover can be useful here as a demarcation criterion between a number of ways "theory" can be employed. In some academic disciplines, theory has more to do with providing an interpretation of various kinds of activity or features of the world so that some new phenomena can be revealed. Maybe an analysis of various patterns of speech in a community can be seen to reveal important background assumptions of that community, and sometimes "theorizing" is a way of capturing the activity involved in making it possible to be aware of those assumptions. This use of "theory" has its own life and vast disciplinary context, one that is importantly different from what will be found in these pages. Here the use of "theory," although broad, is constrained in different ways from much of what is found in other disciplines. It would be silly to say that one use is correct and the other not, and it would also be silly to suppose that there is nothing to be learned about one way of

deploying the concept theory from studying other ways, for there will be important points of contact. However, STEM is a natural domain of application for one way of thinking about the concept, and there is utility for students in fields broadly under this umbrella, or who are trying to learn about topics related to those fields, to have a ready and broadly unified resource for orienting themselves to the way theory is used and developed in those fields. And as an aside it is the one that hews most closely to my own disciplinary competence.

The Organization and Rationale of the Encyclopedia

My main aims for the encyclopedia are two. On the one hand, I want users to find here examples of the various technical and conceptual components of what it is to be a theory, in general terms and not merely as these theories appear in and are used by various STEM focused disciplines as a way of organizing, grasping, making use of, critiquing, and expanding our knowledge of some subject matter. To reflect that part of the aim included here are a number of entries that are concerned with theory itself, in some way detached from any particular subject matter concerning which one might construct or employ a theory. On the other hand, I want users to see the way that various STEM disciplines theorize about their subject matters, both how they make use of existing understanding of what theories are and how they function and how the individual disciplines, by attempting to make theories adequate to the peculiarities of their subject matter, fruitfully extend the very meaning of what it is to be a theory. While these subject matter entries will contain framing material about the theory of their subject matter, their main task will be to illuminate what role theory plays in the discipline and what insights into the nature of theory follows from that illumination.

The entries for the *Encyclopedia of Theory in STEM* range widely. There are 173 entries comprising nearly 625,000 words of text in entries ranging from 1,500 to 7,000 words. The entries have been grouped into 13 categories: there are four broad categories with several further categories grouped under two of them. The categories and their respective entries form the Reader's

Guide, which follows the List of Entries in the front matter of the encyclopedia. The categories are also listed below. I have chosen to group according to discipline, widely understood, as the most perspicuous way of navigating the topics of the encyclopedia. There is inevitable categorical overlap in a number of disciplines, and some inevitable awkward fits given our scope constraints, and the fact that some of the disciplines considered here are generally thought to be situated in non-STEM-covering disciplines, but seemed necessary to include for reasons of coherence.

The first division in the structure of the encyclopedia is between *general* matters having to do with science and theory and *specific* matters having to do with particular disciplines within STEM.

I. General Theory of Science: Here you will find entries having to do with the nature of science, including its authoritativeness, the way its claims are tested, in short the basic conceptual features of the scientific enterprise as a whole.

II. Nature and Structure of Theories: Here the discussion remains general and at a high level of abstraction but the focus is more specifically on the nature of scientific theory. What kind of thing is a theory? How is it connected to other things we do in the sciences? What have theorists about theories learned over the last century from science and from analysis of science, and what has science itself learned from such theorizing.

Turning to the more specific disciplines we see the second division, between disciplines more on the empirical side of things and those on the formal side. Here are found discussions both of matters having to do specifically with the day-to-day features of these disciplines and of general issues that frame and clarify their scope and limits. While these entries give accessible overviews of the subject matter of the disciplines, those overviews are no substitute for extensive study of the disciplines. Instead just enough is presented to make it possible to understand the role of theory in these disciplines.

III. Formal Disciplines: These disciplines are less grounded in empirical data and more focused on concepts. But that is not to say that empirical matters can be entirely neglected. Even in logic and

mathematics, but especially in computer science questions of resources and the role of complexity make it impossible to fully detach oneself from facts about the world. Even so entries here are more focused on structural features of theories, in addition to specific disciplinary matters. This topic is further divided into:

1. Computer Science
2. Logic and Mathematics

IV. Empirical Disciplines: The empirical disciplines as well are not monolithically empirical. Constraints from the nature of mathematics and logic have an impact on the kinds of theory that are possible here. But these entries are more directed to specific developments in observationally testable domains as well as to the connection between theoretical and observational features. This topic is further divided into:

1. Biological Science
2. Chemistry
3. Cognitive Sciences
4. Earth and Space Sciences
5. Engineering
6. Physics
7. Technology

Acknowledgments

This project would not exist without Geoffrey Golson, who initially approached me about trying to sort out what an encyclopedia in this neighborhood would look like. His strong leadership was crucially important in the early stages. As work progressed, the value of the editorial acumen and diligence of Diana Axelsen would be hard to overstate. This project has been long in the making and has had to be reconceived a number of times. Andrew Boney and Sanford Robinson were wonderful collaborators in those efforts of revision, and the encyclopedia benefited at every turn from their contributions. Tamara Tanso provided invaluable assistance to keep me on track and up-to-date with the entries, and the behind-the-scenes support from Sage staff especially made bearable the many quotidian tasks required for such endeavors. Christian Golden's contributions resonate through all these pages, and I thank him profoundly for his good humor, his understanding, and his powerful work ethic. Finally, Natalia makes everything possible and worth doing.

James Mattingly

A

ABDUCTION

Abduction is a form of reasoning distinct from deductive and inductive reasoning. It has often been referred to as the *commonsense* approach to reasoning because it is used in everyday life as well as in scientific argumentation. It has also been called *inference to the best explanation* because people reason from something that has been observed to an explanation for it. The philosopher Charles Sanders Peirce (1839–1914) first described this form of reasoning as *guessing* because he noted that you must leap to a possible explanation without knowing with certainty whether or not it is true. Abductive reasoning is a critical notion in philosophy, including the philosophy of science, as well as that of history, law, and many other disciplines. It is also a basic function of the human mind in everyday life.

Abduction in Everyday Life

Abductive reasoning is used in daily life as a commonsense approach to explaining anomalies. One of the most common examples given is that of walking out of a house to find that the grass in the lawn is wet. Because the grass is wet, one may infer that it had recently rained. If it had rained, then the fact that the grass is wet would be nothing out of the ordinary. That it had rained explains the fact that the grass is wet.

Another such case used to illustrate the process of abduction is that of a faulty light fixture. If one

comes home and flips a light switch to *on*, but the light does not turn on, then one may infer that the power is out or the breaker switch has been flipped. Suppose that, although the light is still off, one sees that the clock on the microwave is on and appears to be functioning correctly. If the power were off in the whole house, then this contradiction would not occur because the microwave clock would be off as well. Now, given this new evidence, one may infer a simpler explanation to account for the light being off, namely that the light bulb has burned out and needs to be changed. In this way, abduction is the process of inferring explanations to account for the evidence or facts that are observed. The explanation can never be proven but rather only inferred.

As a generic tool of human reasoning, abduction has been of interest to philosophers because, unlike deductive reasoning, abduction is not a formalized system of proofs. In fact, the subjectivity required to decide which explanation is best has been one of the difficulties in applying abduction to science and other domains.

Abduction in Use

Abduction is commonly used in philosophical inquiry, in belief revision, in academic and professional disciplines such as medicine and anthropology, and in work-related reasoning. Philosophers of science also draw on abduction as *inference to the best explanation* to be one of the primary tools in scientific realism. Abduction is a component part of human reasoning. There have been attempts to

formalize abductive reasoning to meet the needs of particular jobs or sectors of society. Some decisions require a type of validation, or rules to decide which possible explanation for an observed effect is best. On the most basic level, abduction has no such rules. It is minimalistic in this aspect and allows for subjectivity in determining the best explanation, often leading to revising previously held beliefs. For the hypothesis to be a useful one, it should be explanatory, testable, and economical. The simplest explanation is usually expected to be the best, though the subjective view can never escape the possibility for error. Below are several areas of application, and many of the uses of abduction take place among practitioners or clinicians within a particular field.

Logical Reasoning

Logical reasoning has often been split into *deductive* and *inductive* reasoning. The former begins with reasoning from a general premise to an entailed, or necessary, conclusion. There is room for error if the formal rules of logic have been followed. The latter, on the other hand, is reasoning from specific evidence or premises to a probable conclusion. The rules are not formally set out, but evidence can be collected until it sufficiently can support a conclusion.

Abductive reasoning, according to Peirce, provides a third type of reasoning by which one reasons from a conclusion to a possible explanation. This presents some particular difficulties in the realm of formal logic. Formal logic would propose that the process of inferring is deductive, as in the instance that follows:

All bachelors are male.

John is a bachelor.

Therefore, *John is male.*

Formally, this is written as follows where A is the antecedent and C is the consequent:

$A \rightarrow C$

A

—————

$\therefore C$

In this example of *modus ponens*, we see that given the two premises ($A \rightarrow C$ and A), we must conclude that the conclusion (C) is valid. Whether or not it is true is not a concern. Logical validity is established by adhering to certain rules of deduction. Reasoning, then, happens from the given premise to infer a necessary conclusion. Abduction, however, operates in the reverse.

Abduction begins with a given conclusion or consequent, C and then seeks to infer an explanation for C. This is the formal logical fallacy of affirming the consequent because there is no guarantee that by knowing C one can infer A. That is, returning to the example above, that if *John* is male, there is no guarantee that John is a *bachelor*. Thus, abduction is a form of inference that violates formal logic, but is nonetheless critical to human thinking and philosophical reasoning. Formally, this would be written as follows:

$A \rightarrow C$

C

—————

A “Invalid”

While it is clear that abduction and deduction are quite different types of reasoning, the distinction between abduction and induction is less clear. Since inductive reasoning is the process of learning from example, some have proposed that induction is only a case of abduction. That is, inductive reasoning can be reduced to the more primal abductive reasoning. Other philosophers, who view induction as creating a theory to account for facts, have proposed that abduction is actually only a case of inductive reasoning. Peirce’s triad of reasoning can be found to have overlap in actual use. Thus, some have proposed to use the terminology of *explanatory reasoning* to account for the specific process and product of abduction specifically.

Medical Sciences

The medical sciences make use of abduction, especially in clinical practice, through observing the symptoms of a patient and reasoning as to what might have caused the current condition. A

physician may attempt to explain the cause of several symptoms experienced by a patient. Sometimes, the coexistence of several symptoms may complicate the diagnostic process as a doctor seeks to identify the root cause. Usually, the explanation that seems to explain all of the symptoms is preferable to diagnosis of several causes, thus drawing on abductive reasoning's simplicity to pinpoint a probable cause that can then be treated. Diagnosis and clinical evaluation are examples of abduction in medicine.

Law

Legal experts and lawyers often utilize abductive reasoning. Specifically within criminal cases, a jury makes a judgment regarding whether the prosecution's case sufficiently explains the evidence. The burden, then, is on the prosecution to present a plausible abduction that a judge or jury could endorse as a true narrative of events leading to the crime. The defense, on the other hand, needs only to present an alternative abduction or cast reasonable doubt on the prosecution's explanation of the evidence, to secure the verdict of not guilty. Developing a theory that can be inferred from and explain the evidence is critical in jurisprudence.

Statistics and Applied Mathematics

Abduction has been influential in applied mathematics and inferential statistics. Bayesian inferential statistics, for example, has been a useful way to make decisions based on statistical data. Through statistical evidence, one could reject or accept a hypothesis depending on whether the probability is sufficient for a particular cause to have produced the observed effect. The level of probability represents the most likely explanation, and tells the statistician which hypothesis is most statistically likely, though not necessarily the best, explanation for a consequent. This helps to remove some of the subjectivity innate to abduction. It restricts *the best explanation* to that which is *most likely*.

Abduction also has been used to develop artificial intelligence in computer programming. Parameters for abductive processes can be set, which would allow machines to analyze data and make inferences to explain that data. By modeling

artificial intelligence with abduction, machines can mimic human thinking. Abduction allows for the detection of faults in computer systems, as well as belief revision. This is contrasted with deduction, which would require preprogramming all possible data so the machine can abide by the formal rules of logic.

Philosophy of Science

The influence of abduction as an area of study is perhaps most clearly seen in the philosophy of science. Since the emphasis in abductive reasoning is to infer possible explanations, it can be seen that abduction does not lead to proof or certainty. As noted in the logical fallacy above, one cannot determine the antecedent from the consequent with absolute certainty. One may only infer that the antecedent is a probable cause for the consequent because the presence of the antecedent would sufficiently explain the consequent. Abduction, then, has been foundational in the area of scientific reasoning and, more broadly, what counts as science. Biological diversity, for example, can be explained by many theories. Two of the most debated are Charles Darwin's account of natural selection and creationist accounts of a divine maker. Though either of the two could serve as reasons for biological diversity, the majority of modern-day scientists have appealed to abductive reasoning to validate Darwinian evolution as the operating theory. Since one could claim that Darwin's approach sufficiently explains biological diversity, and is more plausible than a divine maker, scientists reason that the best explanation for biological diversity is natural selection. Science, then, allows for uncertain and unobserved possible causes to be taken as operational *truth* or *fact* insofar as they explain the evidence well enough. This necessarily introduces a degree of subjectivity.

The Subjectivity of Abduction

Abduction has been the target of some critique, specifically regarding the inherent subjectivity. For example, the association with abduction as the *inference to the best explanation* would require an interpretive move as to what is considered the *best* explanation for the accepted evidence. Additionally, it has fallen under criticism because it is used as a

form of knowledge discovery, not as scientific verification. Thus, abduction is sometimes seen simply as hypothesis forming, and not as a valid form of logic or hypothesis verification. In epistemology, abduction can never achieve *truth* or *proof* claims but can only propose possible explanations.

A Scientific Example of Abduction

Abduction is a fundamental concept in philosophy of science. Examples of abduction can be found frequently in scientific inferences. However, one example that serves to illustrate the point is the scientific discovery of the earth's orbit and rotation. Through observation of the sun, moon, and stars, one would be tempted to think that the earth is the center of the universe and that celestial bodies revolve around it. Ptolemy's (ca. 127–145 C.E.) geocentric view was certainly influential, and it was accepted as true since it best accounted for the evidence at hand. Surely, this is what the ancients thought and indeed how they lived their lives. They observed the phenomena that the sun rises in the east and sets in the west, and the most clear-cut explanation is that the sun revolves around the earth. Some observers sought to explain that it was not the sun that was moving, but the earth that was rotating. Philolaus, the Pythagorean (470 B.C.E.–385 B.C.E.), for example, attempted to account for the same observance by theorizing that there was actually a non-earth fire-center around which the sun, moon, and planets circulated. The view was quite complicated and largely dismissed. Others had thought it possible that the earth rotated, thereby giving the appearance that the sun rose and set, but these views had failed to explain all of the cosmic observations and left early scientists believing that geocentrism was the best explanation. It was not until Nicolaus Copernicus (1473–1543 C.E.) developed his heliocentric view that the seeming anomalies in the cosmos were better explained.

Prior to Copernicus, no system naturally explained retrograde planetary motion where, at some times of the year, planets would seem to move backward in their orbits, and then forward again. Ptolemy's system needed to appeal to *epicycles*, the idea that planets were on smaller orbits which were themselves on larger orbits around the earth, to explain the qualitative features of

retrograde motion. Thus, the models presented were highly complicated and made little theoretical sense though they were inferred from the observational evidence. When Copernicus developed his version of heliocentrism, he made inferences from his observations that the way to best explain the celestial movements would be if the sun was in the center and all of the planets revolved around it. This would make some planets appear to move backward because the earth would catch up to them in the orbit and bypass them. Copernicus' system also used epicycles, in fact just as many as did Ptolemy's, but only for *quantitative* features of things. The explanation for the observations was then simplified. Surely, the claim that the sun was the center of the solar system and that the earth revolved around it and rotated on its axis was not without its challengers. But through further scientific validation it was commonly accepted, verified, and improved upon. What began with observation of the sky ended with an inference as to what could possibly account for these observations. No one could actually sit on the knees of God, so to speak, and see the universe's workings, but from one perspective the workings of the universe could be inferred. Thus, science, as well as philosophy, relies on the inference to the best explanation, or abduction, to understand what may cause observed effects.

ABSTRACT KNOWLEDGE

The term *abstract* originates from the Latin *abstractus*, from the prefix *ab-*, meaning “from,” “of”; and “*trahere*,” which means “pull,” “drag away.” It refers to the mode of thinking that allows for the isolation of elements. The topic of abstract thinking can be examined from a philosophical, psychological, and even a neurophysiological standpoint. It generally assumes that the individual is capable of mentally deconstructing a whole into its parts, in order to analyze a situation simultaneously from different angles. In this way, the practice of abstract thought leads to abstract knowledge, which builds upon the individual’s ability to find common properties among elements or ideas, to plan and assume hypothetically, and to think and act symbolically.

Abstract Thought and the Human World

Among the disciplines that study abstract knowledge are biology-related sciences. Ever since Charles Darwin’s (1809–1882) theories of natural selection emerged, scientists have tried to identify which physical elements differentiate human beings, and their thinking processes, from those of other animals. Theorists believe that as humans created increasingly complex social models, these led to more conceptually sophisticated forms of thinking and knowledge. In order to survive and thrive, for example, humans had to develop ways of understanding the world from multiple perspectives, to draw inferences about social patterns, and regulate their own thinking and emotions according to normative group standards. Understanding and incorporating societal cues and norms form the trove of abstract knowledge that allows humans to navigate the social world around them. Language and culture, for example, were born from the need to cooperate and create complex thinking models in order to grow. What differentiates humans from other animals, as some scientists propose, are forms of thinking, learning, and cognition engendered by collaborative and communicative interaction. These interactions rely on information constructed from symbols and assumptions, which require the capability of abstract thought.

In time, humans developed cognitive capacities far more powerful than was necessary for a hunting-and-gathering group to cooperate and survive. Darwin believed that the capacity and use of language might have shaped the highly complex human brain. Subsequently, however, both biology and the cognitive sciences long evaded the issue. Some behaviorists perceived abstract thinking simply as normal animal communication rather than as manifestations of intelligence and language. The brain, working mechanically, was capable of self-organizing in order to save and process new input, such as words. Words, however, are inseparably tied to the concepts they represent. As such, they are part of a cognitive process that merges thinking and words into symbolic representation and meaningful combinations, so as to form a learned language. Therefore, language is considered one of the many instances of human abstract knowledge.

Psychologists have also been interested in developing theories of abstract knowledge. Abstract thought is different from concrete thinking, which is based on real, lived experiences. Early in life, individuals come to understand their daily experiences as real and as based upon interaction with concrete objects. In time, they begin to develop abstract thinking, that is, their own ideas or concepts. It is relevant to mention the work of Swiss psychologist Jean Piaget (1896–1980), who posited that abstract thinking actually develops at around 12 years of age. At this point, humans move from concrete thinking to being able to mentally explore abstract or immaterial ideas. Before that, children are more reliant on concrete thinking. An example of concrete thinking would be the case of very young children who believe that if they cover their eyes, they cannot be seen by others, because they, themselves, cannot see. Unless they have some mental impairment, however, adolescents and adults can understand abstract concepts, such as comprehending that the phrase “a bad taste in my mouth” can refer to a feeling that something is false, deceitful, or unfair, rather than the literal feeling of having a disagreeable taste in the mouth. In other words, abstract knowledge makes it possible to comprehend metaphors and similes as symbolic representations or approximations of ideas. Not all metaphors, however, refer to abstract ideas. The phrase “Get

out of here!” may have a real as well as a metaphorical meaning, the latter referring to an expression of incredulity. People can understand the difference because, inevitably, abstract knowledge is often built upon concrete concepts.

Early philosophical concepts of abstract thinking were first developed by the ancient Greek philosopher Aristotle (384–322 B.C.E.), especially in his theory of universals. Abstraction is a mental activity in which a conceptual property is detached from the whole, so that it may be reflected upon and analyzed, separated from the rest. Whereas Aristotle’s teacher Plato (ca. 429–348 B.C.E.) believed that all objects and ideas had an essence or pure form, which could be perceived intuitively by humans, Aristotle posited that universal ideas exist but that these must be founded upon empirical data or observation. In other words, abstract knowledge must be built upon concrete information. In that way, the idea of *tree* comes from the experience and comparison of many trees, from which aggregate an individual may extrapolate a general concept of *tree*, which shares the characteristics of what they all have in common. It is then by comparing multiple objects that a property considered shared by all may be isolated or abstracted, and the isolated object is a universal. The individual then forms an idea of what a tree, which represents all trees, is. This becomes abstract knowledge, based upon exercising abstract thinking. Abstract thinking is not necessarily based on concrete or material experiences but on the capacity of making projections and building conjectures on a purely abstract and intangible plane. In this sense, many also call it *theoretical*, considered separate from material or concrete existence. One example of abstract thinking, for example, is developed in mathematics and physics, as well as in many philosophical concepts that deal with intangible ideas. Others have compared abstract thinking with the metaphorical plane, which implies the ability to represent ideas symbolically.

It is important to highlight that mental representations of real objects are aided by language. Abstract knowledge is based on formal schemas, which are thought units by which knowledge is represented. Schemas make it possible for people to have foresight and think in terms of probabilities. They also allow the people to categorize and

integrate new information. Abstract thinking is fundamental to all human beings because it allows the capacity of induction and deduction, to synthesize information, and to extrapolate what is important to learn from all situations, as well as to compare, arrive at conclusions, and engage in critical thinking. In short, abstract thinking builds up abstract knowledge, which allows individuals to interpret the concrete phenomena they come across. One of the characteristics of higher level abstract thought is the capacity of simultaneously observing myriad details and evaluating various functions, as well as processing several problems, defining priorities, and responding to several tasks. Besides judgment, foresight, and reasoning, abstract thinking is also related to creativity, insight, and mental flexibility in general.

Abstract Thinking and Language

Abstract knowledge relies on language in order to conceptualize intangible concepts, such as honor, freedom, and justice, as opposed to more concrete items, such as table and tree. Abstract language is also necessary in order to relay the ideas behind metaphors, allegories, similes, idioms, and other figures of speech. Concrete language is used, for example, to explain more textual instructions, such as in manuals, medical protocols, or cooking recipes. Abstract language is used to explain more abstract ideas, such as calculus or equations.

Abstract language is also related to relative concepts. There are, of course, many degrees of abstraction. Intellectual development, as noted earlier, is tied to the gradual process of moving from the very concrete to extremely abstract thinking across a wide range of areas. In many ways, both the concrete and the abstract are specific to a particular area. For some experts, familiarity with an area makes the topic, however abstract, increasingly concrete. In this manner, then, abstract concepts can become relatively concrete to some while remaining highly abstract to others. For instance, a mathematician might find concepts of differential equations to be relatively concrete, although they remain abstract to others; an atom may be a concrete entity to a physicist, while it may be considered an abstract concept by nonexperts.

Language is a system of word-based communication that relies on both symbolic and conventional

characteristics and which is complemented by culturally based nonverbal communication and word content. Culture is the framework that mediates social actions. In order to acquire language, humans must move from learning language to developing an internal language, also known as *thinking*. This knowledge, although abstract and internal, is mediated by culture and society. Piaget's theory of cognitive constructivism, for example, views language as an element of symbolic function in society. Language has a semiotic function, a process of articulation between figurative elements and their actions. The figurative elements of language are the signifiers and signified, what the words are and what they mean. Semiotics, a theory of language, is an example of knowledge which uses concrete and abstract ways of thinking, developed by scholars such as Charles Sanders Peirce and Ferdinand de Saussure.

Language and abstract thought, then, are intrinsically related in many ways. Although the ability of children to manage abstract concepts develops as they acquire language, spoken language is not the sole component in abstract thinking. Children who have been born deaf, for example, can understand many abstract concepts even though they may not develop speech language fluently. They can, however, express themselves symbolically by way of signed language and other forms of communication available to them. Abstract knowledge, then, is based on multiple forms of language and communication.

By thinking abstractly, individuals elaborate relationships of meanings, such as similarities, differences, and causalities, with symbolic meaning represented by way of language. There are three general types of thinking related to language: conceptual, judgment, and reasoning. *Conceptual thinking* refers to the representation of an object by way of abstraction and generalization. *Abstraction* provides the selection of the properties of that object which distinguish it from others, and *generalizing* refers to the assignation of common characteristics to all of those objects that share the same characteristics. Generalizations allow for different levels of depth and directions of thought that can be taken. For every problem, there are some specific directions and levels that may be more useful than others. A computer, however, can be programmed to generalize concepts to levels of

abstraction and proliferation that presumably would exceed human capabilities, such as in chess-playing programs. Abstract thought is the skill, and abstract and concrete knowledge provide the tools that enable an individual to identify which directions and levels are more useful, or which direction is the most interesting. It is in these decisions that human individuality often shines forth and in which human imagination often beats the computer program.

Judgment allows the elaboration of premises that will determine the truth or falseness of a conclusion and reasoning allows the elaboration of analysis by establishing the relationship between one or more judgments or premises. Reasoning includes deductive and inductive thinking, in where deduction refers to conclusions that are arrived by way of going from the general to the specific, and induction goes from the specific to the general. An example of deductive thinking might be the formulation of the following: All humans are intelligent. All those present here are human. Therefore, all those present here are intelligent. An example of inductive thinking might be as follows: Copper expands with heat. Bronze expands with heat. Both are metals. Therefore, all metals expand with heat.

One of the most explicit theories relating language and thought is the theory of linguistic relativity developed by Benjamin Whorf (1897–1941). Whorf argued that the language structure used by an individual originates from their particular conception of the world. Different people see the world in a unique way and employ language accordingly. Therefore, an individual's language expresses a person's determined concept of the world. Many scholars believe that the cognition, thinking processes, and abstract knowledge of an individual are inevitably affected by the particular language structure of each person. For Whorf, the range of vocabulary that a person learns influences the range of activities that the person may conceive related to a particular area. It may also influence the range of creativity and abstract ideas that the person may reach. Whorf's hypothesis has two main versions. One states that language directly impacts thought. Another, more nuanced, states that language affects thought when a particular task depends directly on the properties of a specific language system. There is very little in the way of

proof, to date, on the first version of Whorf's hypothesis. Language, however, is generally considered as one of the dominant elements in abstract thinking and knowledge. The abstracting process that is ever-present in language can be considered as representative of this intellectual activity.

Another important theorist who has written on language and abstract knowledge is the Soviet psychologist Lev Vygotsky (1896–1934). Vygotsky's theories on the relationship between thinking, knowledge, and language have had great impact in contemporary psychology, especially in the arena of evolutionary psychology. Vygotsky argues that thinking and language, high-level mental activities, have different genetic and ontogenic roots, yet have developed reciprocally. His stance is the opposite of Piaget's, who believed that both capacities, mental abstraction and language, were directly related. Vygotsky also critiqued behaviorist philosophies of language, finding that they highlighted types of conduct which were conditioned. For Vygotsky, the functions of thinking and language develop independently. He did acknowledge a close relationship between both, based on developmental mental stages, and argued that language could determine the development of thought and other cognitive capabilities, such as abstract knowledge.

Many contemporary experts agree not only that there are innate predispositions toward developing language in humans but also that some language competencies are independent from general cognition. Today, a variety of disciplines, from philosophy to the neurosciences, agree that language is a combination of many different abilities and processes. Neuroscience research, for example, posits that most of these processes may be studied independently of each other, which takes after Vygotsky's proposals; however, this relative autonomy is also based on understanding language as a composite of structures and subprocesses that enable the production of language, knowledge, and related cognitive processes.

Abstract Knowledge and Moral Sense

Many thinkers have long been concerned with the relationship between abstract knowledge and the development of a moral or ethical sense. Although specific differences between morals and ethics exist,

both are concerned with principles, rules of conduct, or habits with respect to correct behavior and with the consequences of wrongful actions. Some experts have taken a biological approach. Recently, some neuroscientists located the seat of concrete thinking and morality—understood as rule-following—in the frontal lobes or prefrontal area of the brain. Others, from a psychological standpoint, examine how people's level of abstract thinking impacts how they develop morality and an ethical sense, with both understood by experts as a kind of abstract knowledge. Some explain that, with higher abstract skills, people become better at looking at the big picture and visualizing myriad and far-reaching consequences. Moreover, people better skilled at abstract thinking are more prone to considering fairness and harm as the basis of ethical norms. Recently, researchers found that when people are thinking abstractly, they are likelier to make judgments on the basis of core values that are applied repeatedly and across many contexts. A recent Yale University psychological study found that participants aligned with the idea that concern about justice and welfare are the core of moral values, particularly when engaging in higher level abstract thinking, such as considering far-reaching consequences or the *big picture* perspective. Views about harm and fairness are elements of human morality that prove more enduring across time than obedience to authority and in-group loyalties, which rely on concrete knowledge. Authority and in-group dynamics are much more contextual factors; that is, based on temporal or situational events, which makes them linked more closely to concrete thinking.

Moral foundations, however, transcend basic concepts of harm and fairness and physical brain functions and capabilities. The issue of moral knowledge and its relationship to abstract thinking has been examined from different perspectives by philosophers since the ancient Greeks. More recently, modern philosophers from Immanuel Kant (1724–1804) to Jürgen Habermas have written about abstract knowledge and critical thinking as related to concepts of the common good. Kant advanced the notion of deep abstract thinking in order to develop a personal and political ethics. Critics of this view, however, have argued that a highly abstracted view of morals ignores the concrete circumstances of events and may fall into rigid adherence to abstract principles that do not

take into account nuanced social contexts and complexities. Nevertheless, Kant's work was invaluable in positing that only freely chosen actions can be moral. Humans, however, cannot freely choose any type of conduct that is dictated by laws that they cannot comprehend nor control, which contradicts the biology-based behaviorist model. Because each moral human behavior must be reasoned, in the Kantian view, it places the onus of a moral sense on abstract thinking and knowledge.

Habermas (1929–), like Kant, views morality within a framework of rational principles. Reasoning, one of the abstract modes of thinking, is of essential importance in preparing for moral action. Morality itself is the consequence of acting in a way that reflects a stable will in the midst of constantly changing events. In other words, moral action is based on reasoning and remains constant through different concrete contexts. Other modern thinkers equate ethics with mathematics, in that both are based on abstract concepts and universal principles. It is important to note, however, that applied ethics are always related to real cases, which brings individuals back to the concrete and contextual.

Most experts believe that in order to develop an ethical and socially responsible citizenry, it is necessary to cultivate not only their critical thinking skills, foresight capabilities, and moral imaginations but also the tools to act on what is ethically correct. There are concrete ways of developing these skills, such as engaging in punishment and rewards in order to foster mechanical learning of what is right and wrong. These, however, can go only so far, and often fail to provide individuals with the information, knowledge, and abstract thinking skills necessary for more profound moral decisions. It is also important to cultivate the abstract knowledge, concepts of justice and democracy, for example, that fosters the desire to be an ethical citizen of the world. Critical thinking skills, which are fundamentally based on abstract capacity, are crucial to developing an ethical education, moral will, and imagination or abstract knowledge necessary to engage in empathetic interaction with others.

Although most scholars often separate the fundamental thinking processes into concrete and abstract, they are not strictly separated. People often begin a thought process by engaging in concrete thinking skills and need concrete examples in order to

understand abstract concepts. Terms such as freedom, morality, racism, hate, and others are highly abstract and can mean different things in different social contexts. It is necessary to contextualize with concrete examples so that people may understand how the concept is being used. The human mind is formed by a network of very rich and complex processes; striving to separate clearly its myriad thought forms and activities is often nearly impossible.

Developing Abstract Knowledge

Thinking strategies, from abstraction and generalization to synthesis and evaluation, serve humans in interpreting reality. Higher levels of thinking depend upon skillfully combining concrete and abstract mental processes; that is, transferring what is learned in one context to another. For example, learning the categorization of elements in a science class or the organization of an essay in an English class may be skills used in organizing information and content in a social science class. Some individuals are more skillful than others at building abstract knowledge, which may be the result of a wide range of factors. Some of them may be to natural predispositions, and extreme cases of difficulty in abstract thinking may be related to mental illness, frontal lobe injury, and other impairments. While there is no known specific treatment that will develop all forms of abstract thinking, some experts posit that it is possible to practice some exercises that may help, such as logic problems, mathematics puzzles, and other brain teasers. However, these are of limited use. The brain and mind processes are highly complex, and while an individual may be a proficient abstract thinker in one area, they may remain a very concrete thinker in others. Thus, somebody who excels at mathematics may have difficulty in literary theory. Exercises that help in one area of abstract thinking may not necessarily improve in others. Other strategies that may help with improving abstract thinking skills are memory problems, problem-solving, organization techniques, and cognition.

In some cases, people can adjust the environment to help concrete thinkers better understand information and content. Some of these include adopting concrete language, avoiding metaphorical concepts or deep levels of abstraction, and always explaining abstract concepts in relation to concrete

examples. For example, a complex social hierarchy system in a different part of the world, which may seem extremely complex to a concrete thinker, can be made easier to comprehend by explaining it in terms of kin or social systems with which they are familiar. It is important to understand, however, that for a very concrete thinker, the progress achieved by these exercises may not translate to other content, academic, or social areas. It does, however, help the individual build up their repository of abstract knowledge in at least one area.

It is a common assumption, to a certain extent, that before the inception of adolescence, very young children do not have any ability to engage in abstract thinking. This is a misconception. Young children begin to develop abstract thinking skills and knowledge through their early pre-school years. One of the ways in which they develop these is through pretend play, which can be taken to a high level of abstraction. For example, children may take an ordinary object to represent something entirely different. They can also engage in complex role-playing conducts which are, basically, variants of symbolic actions. Children learn how to read and to add and subtract by way of symbols, developing the skills that will help them later on to develop more abstract reading comprehension and mathematical skills, such as problem-solving, algebra, and calculus. There are many ways in which children engage in abstract knowledge building. Alphabets and numbers are, after all, symbols. They represent something other than their form, such as sounds and quantities. Children also draw doodles they take to represent something else. When told stories, they can imagine scenes and offer different takes on the storyline. All of these skills involve abstract thinking, which are the necessary stepping-stones to developing strong problem-solving and critical thinking skills later on. It will also be important for developing empathy and a moral self. Abstract skills enable individuals to place themselves in the position of other people and imagine their suffering; in other words, they help develop empathy. These are some of the reasons why experts recommend encouraging and aiding young children to develop abstract thinking skills through a variety of educational programs, games, and exercises.

ABSTRACTION

Abstraction is defined as the development of cognitive signifiers that represent physical objects, actions, or constructs. The word *chair*, for example, might conjure up an image in the mind of a real-world object, a chair. The mind's chair is an abstraction while the physical chair is not, they are different in that one is an approximation, a set

of rules, and the other is an entity. Abstraction is the development of a prototype, or set of rules, that may focus only on a limited set of details. Therefore, it is also integral to the understanding of any theory. We cannot discuss evolution, morality, or quantum dynamics without abstraction. Abstraction is not, however, just a mental process, it can be physical as it is in language, math, computer science, and genetics. Abstraction is sometimes defined as mapping a representation of a problem within another representation. Abstractions are meant to provide insights and clarify a series of observation or to provide a framework for future data analysis. As observations morph, based on an increasing number of documented exceptions, we modify the model little by little until eventually a new model is devised which supplants or augments the original model. This new prototype becomes an added tool with which to measure reality. This entry focuses on defining abstraction through a series of historical usages, defines several schools of thought regarding abstraction, and addresses the concept of abstraction in several commonly studied theoretical fields.

The Theory of Abstraction

It is a little circular that we must have a theory regarding abstraction, as abstraction is a process by which our minds develop theories, that is, by the organization and categorizing of subjects. The term itself is derived from the Latin word *abstrahere* or *to draw away from*. Within the definition of abstraction, we must presume that anything that we look at and interpret with our mind is an abstraction and therefore, so too is the theory to define the term *abstraction*. Abstraction is, in simplest terms, to distill what is generalizable and important about a subject. Our mind does this all the time, in processes that we have only begun to define scientifically. To clarify this concept, let us go back as early as we can in human history. Paintings on cave walls may be one of our first look at human abstraction: a man, a killing tool, and an animal painted on a cave wall. What we have presented is a prototype of the simplest elements necessary for *the hunt*, an abstraction. The three objects—man, tool, and animal as target—existed first, and from it we abstracted the hunt. It

is a distillation of something general, with superfluous details taken out. We can see this in the picture, and we can readily understand it, but it does not show us reality, it shows us an approximation of reality which we call abstraction. Terminology is important when we describe the subjects of abstractions; an abstraction is said to be *conceptual* if it abstracts a concept and *objectual* if it abstracts an object. Therefore, we know that abstraction can indicate at least two types of subjects: objects and concepts. But more than just a generalization of a subject, abstraction is an attempt to define the essential in a subject, winnowing it down to only what is necessary. The following sections aim to describe each of these principles, generalization and essentials, through a survey of historical perspectives.

Language

Language is the most primal and fundamental example of symbolic abstraction. Human languages are at the root of all other complex abstract modeling. Words are the representations of subjects; concepts and objects as encountered above. They reside both in our minds and on our tongues. Linguists believe that abstraction is only possible as a consequence of acquired language, that is, verbalizations. The concept of *red* is an abstraction, not possible, for instance, without verbal ability in which all objects that are red can be divided from other objects only by this shared feature. Before language, one can argue that there were apples, but not *red* apples or *green* apples, as the feature red could not be segregated from the object by a mental representation until it could be generalized to define a specific detail. Written language in turn made visual symbols of sounds, further categorizing the detailed parts of words. Natural language constructs used in language and linguistics are a well-established and formalized form of symbolic concept and object abstraction. Work from the visual languages has suggested that abstraction occurs within this framework as well. A word or hand gesture is used as a representation of a concept. Furthermore, in linguistics, the separation of concepts into deeper categorization, described as the parts of speech, allows for even more elegant rules to be derived about the nature of language itself as well as to foster easier

learning of syntax and grammar. Generally, knowledge acquisition via model construction is accomplished through analysis of verbal or written terminology; in other words, the abstraction of language, as we will see from the discussion of the historical root of abstraction described in the next section.

Ancient Abstractions

The ancient Greek philosopher Parmenides of Elea, in his one surviving work, focused on the power and human tendency toward abstraction. In the poem he talks of the *way of truth* and the *way of opinion*. Truth, he says, is timeless, unchanging, and *what-is*, but opinion, he says, is the way our sensory faculties lead to constructs, mostly false. Parmenides's *opinion* is what we call abstraction, and like his view on *opinion*, what we construct though abstraction is mostly false, or at least approximate. Later we will see how nature and then science have played a role in rectifying at least some of the falsehoods in our abstract models. The Athenians attempted to make a world that was as *real* as possible. Paul Feyerabend described the Athenian view of abstraction in five principles from Aristotle. The first is that the boundaries between reality and appearance cannot be established scientifically. There is a normative or *existential* component. Second, the normative component leads to debate as to the true nature of reality. Third, different lifestyles lead to different interpretations of reality. Fourth, science contains different traditions, and scientific viewpoints are not the only viewpoint. Indeed, many nonscientific cultures suggest that there is more than one way to define a reality that works. And finally, the fifth premise is that science is incomplete and fragmented. What this means is that to the ancient Athenians the world is highly parsed, and no unified view of reality exists. Today we just have more elaborate fragments. Reality then, to the ancients, is an abstraction seen differently depending on what details we make important.

Of note, it was the theological scholar William of Ockham, known for the principle referred to as *Occam's razor* (viz., explanations that posit fewer entities are to be preferred to explanations that posit more), who pioneered the field of *nominalism*, in which he claims that universals, generalizations, are the products of abstraction and have no

extra-mental existence. Nominalism is a position that suggests that only specific objects exist but not universal entities; this stands in contrast to the position of *nihilism*, which denies that even simple objects exist, only mental images do. Finally, *realism* is in contrast to both nominalism and nihilism, in that it suggests that all things are physical, not mental. In these metaphysical world views, we are confronted with the notion of a mental and physical plane. Each philosophy, however, intimates the existence of the abstract, with varying degrees of grounding in the features of the physical world. Though greatly simplified in this discussion, abstractions are considered the properties of real objects in realism, mental interpretations in nominalism, and the only thing that exists in nihilism. Abstraction in this sense means that objects and concepts may not exist before we sense them or at least as we sense them. The idea of something from nothing has been a fundamental conflict between secular and religious scholars, but with the concept of abstraction we find the ability to take not only what is real and formulate nonexistent prototypes (i.e., universals), but also the ability to create patterns, where before there was nothing at all.

Natural and Scientific Abstraction

The behaviorist view is that abstraction only has bearing on reality in so far as it affects actions. Behaviors can be predicated by abstract thought, if we know the abstract model utilized, but it is the outcome that matters. Unlike the aforementioned philosophical viewpoints, *naturalists* believe that nothing exists outside of space-time. From this perspective, all abstractions exist within and as a part of natural phenomena; in other words, everything can be reduced to a physical account, even conceptions. Other viewpoints, such as Ockham's, which state that there are certain things that cannot be rationally examined, are not interpretable by our rule sticks and therefore not useful in theory design. Nature, however, played an important role in the development of abstract worldviews before a systematic scientific perspective came about. As mentioned previously, Aristotle believed that while many viewpoints existed, they were all required to be successful if they were to persist. Abstractions were valuable in so far as they helped to predict or guide successful human behavior. In

many cases, these early abstractions were the models for morality and ethics on the cultural level. For example, the perception of the Egyptians that beer was a product of the gods led to widespread consumption, which in turn kept bacteria at bay and paid for the building of the pyramids. Abstraction, from this perspective, is a view of the world that allows for better control of it.

Another natural view of abstraction comes from the art world, where abstraction has been emphasized as an inspiration for all artistic forms. Abstract art is not, as the uninformed may assume, a mass of scribbles on a canvas but is inspired by an artistic attempt to eliminate unnecessary elements while retaining the universal. In art theory, abstraction is taught to aspiring artists as the process of stripping down to the essential. It is thought that some abstraction occurs in every form of art, and it is this essence that the artist is intending to elucidate with their work. This is in effect a reversal of nature impinging on our internal model; in art we have an external model reflecting nature's essence. In both domains, we find the first seeds of scientific abstraction, that is, the beginning of detailed perspectives in the development of better modeling systems.

Science is the way we try to decipher our world into manageable chunks. The formalization of abstract thought into symbolic chunks called *language* paved the way for a deeper analysis of reality. We have heard that Aristotle believed that science could not fully interpret reality, that Ockham believed that there were ideas that could not be divined through rational thought, but despite this, the environment influences our model and artists have tried to distill the fundamental in their works. Likewise, scientists have continued to push the bevel incrementally forward. From a strictly scientific perspective, abstractions are the subdivision of data packets, information, into their smallest unit of representation. By systematically categorizing, science has devised abstractions of our world that are superior to the abstractions of the past. Scientific abstraction is meant to better predict the outcomes of our interaction with reality; again, this is achieved by narrowing down to what is essential or universal in a process. One way to do this was to attempt to remove ourselves from the equation, to form a detachment from the principles with which we wish to form theories. The scientific method was one way to achieve

that, and this has been done at least twice more in human history with great success. The first was with human language, described earlier in this entry, and the second was with mathematics. Both of these symbolic systems, which distill objects and concepts into universal icons, are fundamentally systems of abstraction.

Mathematics

Though some have argued that mathematics is a self-contained system, no system that is used to represent another system can be defined as anything other than an abstraction. Mathematics is the second most pivotal example of abstract modeling devised by man and has allowed us to visualize, though symbol, scales of magnitude far greater and far smaller than our bodies could comprehend otherwise. From it, we have developed rocket propulsion, physics, and computer science. While arguably more or less important than language in understanding reality, math most likely could not have been derived without it. Indeed, mathematics is perhaps a better abstract modeling tool than language because it is more detached from human emotions and anthropomorphic properties.

Mathematical abstraction requires utilization of everyday words, but in a very precisely defined relationship to mathematically unique symbols. Additionally, mathematics consists of sets of rules for operating on mathematical objects. Therefore, symbolic objects and concepts are manipulated by a specific set of rules to form a self-contained abstract modeling system. Like all abstract systems, the rules and the subjects are generalized; universals represent other structures. Numbers, for example, were initially mathematical symbols that represented quantity. Later, axiomatic systems arrived that were considered independent of quantity, which emphasized the abstract nature of the mathematical objects and suggested that they may exist apart from external reference. Again, if you recall, abstractions can be representations of real-world objects, such as a *dozen*, or they can be representations of things that do not physically exist; mathematics reminds us of the nihilistic view that nothing physically exists.

One interesting mathematical concept, which we will see again in computer science, is the mathematical *map*. A mathematical map is a function used to describe a class by a specific parameter, such as the

linear transformation in algebra. As such, a mathematical map is an abstraction, which is defined by mathematical abstractions. There are of course many other cases of recursive abstraction. It is math's real-world utility that makes it a powerful abstraction tool, from calculating a monthly budget without cash in front of you to developing a video game using a simulated physics engine.

Psychology

Schema-abstraction, defined in the psychology literature, is the process of learning concepts from examples. Schema-abstraction theories assume that some information is abstracted during learning and stored for classification of new examples. And these theories are distinguished from one another based on how information is characterized, retained, and utilized in the classification of new incidences. In schema-abstraction studies, either a *prototype* model, in which an abstract prototype is constructed and all other examples are compared to it, or an *instance-only* model, in which no abstraction is performed and only training examples are stored, is postulated. Determining the difference between these types of interpretive models has been conducted within psychology research in collaboration with computer science, where the research tools are developed. For example, using a computer mapping program, a series of experiments meant to examine what effect sequence presentation has on conceptual learning was conducted, whereby subjects are asked to devise a rule based on observation of a series of figures given in a specific sequence. However, an explicit definition of the abstraction process has made these studies difficult. For instance, some have argued that learning is dependent on the sequence of presentation of events; others, however, have only seen weak results in experiments looking to replicate this principle. The primary function of schema-abstraction theory investigation is to attempt to delineate which aspects of a model are generalized and when this generalization takes place.

Computer Science

The use of computer programming to generate a number of plausible mappings (*gmaps*) of symbolic object associations has been used in the study

of the cognitive abstraction processes described above. Mapping, in computer science, is derived from the mathematics and is used to describe the process of converting associative arrays of data from one form to another. Typically, these programs consist of several modules including the map generator and the structural evaluator, which acts to providing alternate gmap evaluation scores as well as other descriptive modeling tools. Studies in this area have loosely defined abstraction strategies into two classes *limiting case* models, including exemplars only, and *combination* models, including an IF-THEN-Rule Generator. In computer-aided modeling, investigators can investigate several models at the same time. Each model predicts a different type of mental rule formation and can therefore help to define what part of an observation is being processed as an abstraction. Developing investigation tools is only part of interest for computer scientists in abstraction modeling. The binary code of 1s and 0s represents an attempt to distill the information found in analog data into a simpler form. Combining mathematical rules and computer science has led to the creation of intricate simulated environments, sometimes called *engines*, which have been used to analyze everything from engineering to biology. Computer scientists have used abstractions from web browsing histories to predict customer activity, which has been used by search engine companies to target products to consumers. Another lucrative area of research in abstraction is in the field of artificial intelligence (AI). Indeed, understanding the pieces of information used in conceptual abstraction can influence the design of computer systems to create more efficient information processing, one of many goals in creating advanced AI.

From Cognition to AI

Simpler models act as the starting point for more complex modeling. But in contrast to what one might expect, the derivative symbolism from the simpler models allows us to formulate complex models in simpler terms. Like the mathematical map, this is the nature of abstraction. One abstraction can become embedded in another abstraction, reducing the size of the data. By ignoring the irrelevant details, abstract models take many subjects and combine them into one subject. We have seen

this in philosophy, where Ockham suggested that the simplest solution usually fits best and called that solution *God*. We have seen this in language, whereby one word, such as *chair*, defines a whole category of objects. We have seen it in math, where one number, for example 5, is the defining factor that generalizes a multitude of instances. We have seen how it can be applied to schema-abstraction models in which either a prototype or exemplar exists. We know that computer scientists are using abstractions today to track the behavior of individuals and market products to each individual accordingly. But these are just the beginning. Abstract models beget more abstract models, which again work to condense multiple objects into symbols representative of them all. The biological process of cognition is thought to use abstraction, which is why it created language and math, and is rooted in the symbolic DNA code of four base pairs, which represent 20 amino acids, from which countless protein structures are generated. Several structures of the human brain are called *pattern generators*. Humans intuitively try to associate objects and concepts into clusters called *patterns*; in other words, we naturally abstract. Perhaps now we can see the purpose of abstraction, a storable code that represents a much more complex system. Data are easier to manage in this simpler form and take up less space. Indeed, humans have extrapolated that the ultimate abstractions would be the ones that define all subjects as one essential category: the unified theory, the Big Bang, God, and so forth. Finally, at the forefront of science, individuals are piecing together the processes found in numerous fields to generate an abstraction of human thought that can fuel an artificial mind. Whereas human cognition is still hundreds of orders of magnitude more efficient than the currently most advanced computer operating system, the growing field of AI has an overwhelming need to define abstractions to fit more information into a finite system. These are the yet-to-be-defined abstract information processing algorithms.

Conclusion

Abstraction, as explained in the preceding sections of this entry, is the process of condensing relevant information and disregarding irrelevant information. It is used in commonsense reasoning

in order to simplify conceptualizations and to focus attention on specific details. Our processing of reality occurs in the form of abstraction. Furthermore, language and mathematics, two formalized abstract models, have led in turn to refinement of our abstract characterizations and were required for advanced scientific discoveries in biology, psychology, and computer science. To abstract is to focus on establishing the essential in every system. This is the nature of abstraction: to ever refine and reduce subjects to their simplest and most essential characterizations. Abstraction therefore is one of the most useful tools in theoretical analysis.

ACCURACY

The concept of accuracy is central to the scientific method; this article focuses on how it is employed in scientific practice. In common parlance, a statement is said to be accurate when it is factual. In turn, a statement is factual when it is expressing a proposition that is in agreement with facts or actual states of affairs. In that sense, asserting that

a statement is accurate is equivalent to asserting that the statement is true. Moreover, the term *accuracy* is often used as a quasi-synonym for other terms such as exact, precise, correct, literal, and similar expressions in the same semantic field. However, in scientific parlance, there are significant differences between the meanings of those terms.

The concept of accuracy is closest to what philosophers of science call *approximate truth*. (Other terms used in philosophy of science with similar meanings include truthlikeness and verisimilarity.) This is reflected in the normative terminological proposals of the International Organization for Standardization (ISO, 2012) where the term *trueness* is used to describe the accuracy of a measurement method ($\cdot$). (The ISO standards also uses the term *precision* to describe accuracy. However, we will not follow this usage here since it conflicts with standard usage in mathematics and computer science, where *accuracy* and *precision* are sharply distinguished.) As such, accuracy is a concept that is related to other methodological concepts such as precision, error, and uncertainty, and this article will sketch how the relation is fleshed out in experimental and computational contexts, which are the two main scientific contexts in which assessments of accuracy are required.

Accuracy is a concept used to characterize statements *semantically*, just like approximate truth. Thus, whereas truth (and accuracy in its colloquial sense) is used to provide a *binary* semantic evaluation—true or false, with no admissible intermediate—accuracy and approximate truth allow for intermediary semantic assessments that admit of degrees. But due to its intrinsic vagueness and lack of general criteria of application, the concept of approximate truth has received some harsh criticisms in the philosophy of science literature. For instance, Laudan (1981) has argued that discussions relying on approximate truth are “just so much mumbo-jumbo.” Indeed, what would it mean for the statement *Orgone exists* to be approximately true? Such qualms, however, are dissipated once we observe that approximate truth and accuracy are concepts that do not apply to the semantic evaluation of all kinds of statements.

The scope of application of the concept of accuracy can be rigorously delineated using Carnap’s distinction between classificatory (also

known as *qualitative*), comparative, and quantitative concepts. Firstly, a classificatory concept is a concept that places an object within a certain class. For instance, when we assert that whales are mammals or that electrons are fermions, or when we make an existentially quantified assertion such as “*dark matter exists*,” we are making simple claims about classificatory concepts. Such concepts can typically only be meaningfully evaluated semantically using a binary scale—true or false. Thus, neither the concept of accuracy nor that of approximate truth apply. Secondly, a comparative concept is one for which it is meaningful to provide an ordinal ranking of the degree to which the concept applies. For instance, if we consider the classificatory concept *tall*, we could only assert that a given person is tall or not. With the comparative concept *taller than*, we are now in a position to say that individual *a* is taller than *b*, that *b* is taller than *c*, and so on. However, quantitative concepts are purely ordinal. Thus, the concept *taller than* does not offer resources to assess how much taller *a* is, *b* is, and so on.

Finally, quantitative concepts are those for which there is a numerical value on some scale that is used to determine whether the concept applies. If we consider the concept of distance, we would mathematically specify with a number or a function what the distance of a line segment is. There are many subtleties and complications involved with the selection of a proper scale to assign numerical values as Scott and Suppes make clear in their 1958 essay “Foundational aspects of theories of measurement”. However, the point that is important for our discussion is that if we assert

The line segment has length M (1)

when in fact it would be true to say that

The line segment has length L , (2)

we can give a semantic assessment of statement (1) more refined than just observing that it is false. To the extent that M is close to L , we will say that statement (1) is more or less accurate. We then define the quantity Δ

$$\Delta = |M - L| \quad (3)$$

as the *error*. The smaller the error, the more accurate a statement is. Thus, statements containing quantitative concepts are within the scope of

application of the semantic concepts of accuracy and approximate truth.

However, there is a difficulty related to the assessment of the accuracy of a statement that fundamentally entangles it with a related epistemological problem. Indeed, if we knew what the exact (or true) value of the quantitative parameter in the first place, we would have asserted the true statement. Thus, the problem is that we need to assess the accuracy of statements without knowing which value is the exact one. This epistemological problem is central to two methodologically important branches of science, namely, scientific computing and experimental measurement. We discuss them in the remaining two sections of this article.

Accuracy of Computation

The concept of accuracy plays an essential role in computational mathematics because exact solutions to the mathematical equations arising from the construction of realistic models typically do not afford exact solutions. Numerical algorithms are then used to extract information about what the solution to model equations might look like. However, since the computed solutions are typically not exact, an assessment of accuracy is required to validate results.

Computational errors are essentially of three types. Truncation error amounts to replacing functions $f(x)$ (often characterizing vector fields) and integrals $\int f(x)dx$ (often characterizing the motion of a body in phase space) by truncated asymptotic series in a perturbation parameter ε , that is,

$$f(x, \varepsilon) = \sum_{k=0}^N f_k(x) \phi_k(\varepsilon),$$

for some collection of gauge functions $\{\phi_i\}_{0 \leq i \leq N}$ (see the entry on Perturbation Theory in this encyclopedia). Expressions of this sort have to be truncated, since we often have no closed-form solutions, and it is impossible to add an infinite number of terms in series. Secondly, discretization error is the error incurred by replacing a continuous parametrized flow $\dot{x} = f(t, x(t); \mu)$ in phase space by a discrete map of the form

$$x_{k+1} = \Phi(t_k, x_k, \dots, x_0, h, f, \mu).$$

This substitution is the basis for most methods of numerical differentiation and integration. Finally, we typically do not compute the value of functions using field arithmetic (e.g., the familiar arithmetic of real numbers), since computers cannot handle such infinitary entities. Thus, it is replaced with a finite computer arithmetic known as *floating-point arithmetic* (see Figure 1).

In essence, it involves replacing the real line by a *floating-point number line*. As we see in Figure 1(b), it is not really a line; this is why it is important to consider the role of roundoff error in mathematical representation. All of these computational approximations are made because we can only execute finite, discrete operations on a digital computer.

There are three ways of measuring computational error. (For a more extensive explication of these notions, see Corless and Fillion (2013), Higham (2002), or Deuffhard and Hohmann (2003).) Mathematical problems can be thought of as maps from a set of input data to a set of

Figure 1 Floating-Point Numbers. (a) Structure of Single-Precision Floating-Point Numbers. There Is a Bit for the Sign, 8 Bits for the Exponent, and the Remaining 23 Bits Are for the Fractional Part. (b) Discreteness of the Floating-Point Number Line, With Variable Density

output data, that is, as $\varphi : \mathcal{I} \rightarrow \mathcal{O}$. The mapping itself will typically be given as

$$x \xrightarrow{\varphi} \{y \mid \phi(x, y) = 0\}, \quad (4)$$

where x is the input data, y is the solution sought, φ is the defining function, and $\phi(x, y) = 0$ is the defining equation (or condition). However, as we have seen, when we use a computer for computations, we engineer a modified problem $\hat{\phi}$ so that it can be implemented and efficiently executed on a digital computer using schemata for discretization, truncated, and rounding off. In general, for a problem such as the one in equation (4), the difference between the exact solution y and the approximate solution $\hat{y}$ will be denoted Δy and will be called the *forward error*. The concept of forward error is typically the one that is referred to when people talk about error; when they refer to a computed solution as being *accurate* or *approximately true*, one means that the forward error is small.

Even if the forward error is the most common, in many contexts this is by no means the most insightful, because we have no direct way of calculating Δ when we don't know what y is. For this reason, there are two other measures of error known as the *backward error* and the *residual*. (For the former, see Fillion and Corless (2014), and for the latter, see the article Perturbation Theory in this encyclopedia.) However, whatever measure of error is used, assessment of accuracy is typically done by reference to the forward error. Since it is typically impossible to obtain an exact quantification of the error, numerical analysts typically analyze the algorithms used and prove that the error must be smaller than a certain quantity or function, known as an *error bound*. As a result, even if the exact error is not known, we know that it lies within a certain interval. If the interval is sufficiently restrictive for the intended purposes, then the computed solution is judged sufficiently accurate.

Accuracy of Measurements

The construction of a model susceptible of generating prediction (or retrodiction) and explanation of the behavior of a system requires the

specification of the value for some parameters. Those parameters may be the primitive quantities in which the states of the system are expressed—examples include position, momentum, temperature, pressure, spin, and so on—or some other derived quantity. In either case, the value of this parameter will be supplied on the basis of *measurements*. Nonetheless, no scientist would argue with the fact that all experimental data have some degree of imperfection, in that experimental results always contain errors. As a result, numerical values gathered in experiments are always likely to be wrong (i.e., inexact). This, however, does not imply that the values reported are bad, for they may convey entirely satisfactory information if the measurements are sufficiently accurate. To ensure that inexact values reported are informative, scientists have to diagnose the possible sources of measurement error and must try to design an experimental setup that will ensure that the error is minimized (or satisfactorily small, given what is already known). That is, one must establish the value of a parameter with a methodology that will also make it possible to assess the accuracy of the value.

However, here again it is not possible to exactly quantify the measurement error directly for the value of the parameter being measured is unknown. The key to assessing the accuracy is not to directly quantify the error but to specify an interval within which the error is. Thus, the role of measurements of parameters is to determine (1) a value of the parameter and (2) an estimate of the uncertainty associated with the measurement. The central concepts involved in a theory of measurement are thus the concepts of accuracy, error, and uncertainty.

The discussion to follow is based on the so-called *GUM approach* to the theory of measurement (“GUM” stands for “Guide to the expression of Uncertainty in Measurement”). The relevant technical documentation includes the guidelines of the National Institute for Standards and Technology and the technical reports from the Bureau International des Poids et Mesures. In what follows, the terminology is used according to the International Organization for Standardization (2004).

A measurement is a process involving a *system* and an *apparatus*. The quantity that is subject to

measurement is called the *measurand*. The value resulting from the measurement using a certain apparatus is known as the *indication value*. The difference between the value of the measurand (what is often called the *true value*) and the indication value is the *error*. Again, error is a *semantic* notion, relating to a *matter of fact* relating two numerical values. It is not about what we know, ignore, wish to know, or even can know. It must be distinguished from the *epistemological* notion of uncertainty, since “the result of a measurement after correction can unknowably be very close to the unknown value of the measurand, and thus have negligible error, even though it might have a large uncertainty.” It is important to stress the distinction since they may *appear* identical as both are understood as intervals within which the *true value* lies. All the scientist can do is to provide an *estimate* of the error based on what is known about the system and the measurement apparatus. (“In general, the error of measurement is unknown because the value of the measurand is unknown. However, the uncertainty of the result of a measurement may be evaluated.”)

This is why, in modern expositions of the theory of measurement, the role of uncertainty is given priority over that of error for the formulation of methodological rules. The first step toward a correct estimation of the uncertainty of the results of a measurement is a diagnosis of the possible sources of measurement error, which are of two kinds: (1) random error and (2) systematic error.

They are also often referred to as *Type A* and *Type B* error, respectively. On the one hand, *random errors* are unpredictable. They are variations in the measurements that the experimenter cannot control (or can control only very limitedly). In terms of probability, it is an error that is just as likely to be above or below the real value; so, for random error, averaging a large number of measured values should, in principle, largely reduce the magnitude of the error. On the other hand, *systematic error* cannot be controlled as random error, that is, averaging will be of no help. Systematic error is caused by the design of the experiment. Its impact can only be alleviated by modifying the design; however, it is

often very hard to find a setup that has no systematic error. See Table 1 for examples. Systematic error is particularly problematic, from an epistemological point of view, because there is no way to determine whether there is a systematic error. (“Like the value of the measurand, systematic error and its causes cannot be completely known.”)

Table 1 Examples of Random and Systematic Error

<i>Random Error</i>	<i>Systematic Error</i>
Vibration in the floor → fluctuation in balance	During the time required to measure the mass of a fluid, some evaporates
Air currents → fluctuation in balance	During the time required to measure length, the temperature is not controlled and changes
Electrical noise in a multimeter	Miscalibrated balance will cause all the measured masses to be wrong

Each of the uncertainty components that contribute to the uncertainty of the measurement are represented by an estimated standard deviation, termed *standard uncertainty*. This standard deviation may be or may not be evaluated statistically, as Case A or B may be. We talk of *Type A* and *Type B* evaluation of uncertainty. Type A uses any appropriate statistical method. However, the procedure is not as straightforward for the assessment of Type B uncertainty components:

A Type B evaluation of standard uncertainty is usually based on scientific judgment using all the relevant information available, which may include

- previous measurement data,
- experience with, or general knowledge of, the behavior and property of relevant materials and instruments,
- manufacturer’s specifications,
- data provided in calibration and other reports, and
- uncertainties assigned to reference data taken from handbooks.

Repeating the experiment can be used to successfully control error arising from random effects. By carefully considering the factors mentioned, *replicating* the experiment can be used to successfully control error arising from systematic effects. (It is important to distinguish repeatability and replicability. Repeatability consists in doing the measurement multiple times with the same apparatus; replicability involves changing the apparatus, each having their own systematic biases.)

The task that remains is to find the *combined standard uncertainty* of a measurement result. The combined standard uncertainty, as its name suggests, combines together all the uncertainty components of Type A and B to generate a total estimate of uncertainty. The usual method used to combine uncertainty is the common statistical method used to combine standard deviations known as *law of propagation of uncertainty*.

We have seen that the concepts of error and uncertainty are intrinsic aspects of the values of the experimentally measured parameters. What does the presence of error and uncertainty imply for the mathematics used to analyze such data? The key challenge here is to develop mathematical techniques that permit us to deal adequately with operations on quantities not known exactly. The most basic approach to do this is that based on *significant figures* (or, alternatively, *significant digits*). The idea is easily understood from the following joke:

Bazooka Joe is showing a friend a fossilized bone. The friend asks how old it is and Bazooka Joe responds that it is one hundred million and three years old. “How do you know that?” asks the friend. Bazooka Joe responds “The museum expert told me it was a hundred million years old and that was three years ago.” (reported by Ruekberg, 1994)

The author then explains the pedagogical relevance of the joke as follows:

The author readily admits that the joke is not *very* funny. That it is funny at all is because even children, just old enough to chew gum without swallowing it, realize that something is wrong about Bazooka Joe’s computation: the accurate three years cannot be added to the ball park figure of a hundred million years. (Ruekberg, 1994)

The computation is wrong even if, arithmetically speaking, it is irreproachable. Thus, when there is uncertainty, there is a methodologically important sense of “correctly using mathematics” that differs from the standard one. Understood as a tool occupying a central place in a strategy for the management of uncertainty, the first role of significant figures is to faithfully report the uncertainty in experimental measurements. More precisely, significant figures are a tool to faithfully report the *accuracy* and the *precision* of the results of a measurement, given the *resolution* of the measuring device. It is important to keep in mind the distinction between accuracy and precision. Accuracy is about having the answer right, that is, about having a small error. Precision is about having many digits. For instance, 3.166666666666667 is a very precise (16 digits) but (for many purposes) very inaccurate (two digits) approximation to π . On the other hand, 4.54×10^{-5} is a not very precise (three digits) but quite accurate (precise to the order 10^{-6}) approximation to e^{-10} . Similarly, a measuring instrument can be very precise, and yet inaccurate. As W. Kahan and Joseph D. Darcy (1998) explain, “[p]recision is to accuracy as intent is to accomplishment.” A basic objective of the use of significant figures is to not be fooled by measurements that are more precise than accurate; thus, a basic rule is to not report results of measurements with more digits than are accurate, for those extra digits would not be significant. Precision is a property of a linguistic object (namely, of the numeral representing a number in a given number system), whereas accuracy is a semantic notion. Limiting the number of figures reported to the significant figures is a way to make the semantics transparent by showing it in the form of the linguistic expressions used to report results.

The resolution of an instrument is the maximum error that the instrument produces under prespecified circumstances (e.g., value range, ambient temperature, humidity, pressure). (The manufacturers of equipment often indicate how accurately and precisely it can measure.) However, the resolution cannot be smaller than the precision of the instrument. To illustrate this point with a simple example, if a ruler’s smallest

division is 1 millimeter, then we cannot specify what a length is by measuring with this ruler is to less than half of a millimeter. What we obtain from an instrument with this precision is a number having the format $x.yyz$ centimeter, where x is the integer part, yy are the certain digits, and z is the uncertain digit (there is only one of those, the last one). The last digit is only an estimation. Moreover, under the prespecified conditions mentioned earlier, if the instrument is properly calibrated, then each digit within the precision of the instrument is taken to be significant. Accordingly, *the significant figures of a number are those digits that carry meaning contributing to its precision*, and indirectly contributing to its accuracy, provided that some assumptions about calibration are satisfied. (Of course, if the prespecified conditions of calibration are not met, then the reasoning does not hold.) Thus, the significant figures of a number are the digits necessary to specify our knowledge of that number's precision; and in nice contexts, this also reveals the accuracy.

Whereas this first role of significant figures is to *represent* uncertainty numerically by imposing conditions on precision, the second role of significant figures is to permit the formulation of computation rules to determine how uncertainty *propagates*. Those rules are typically formulated in terms of limits on the numbers of significant digits (or significant decimal places) that may be retained in order to faithfully track uncertainty. Here are some standard rules:

1. Exact numbers do not affect the number of significant figures.
2. For addition and subtraction, the answer contains the *same number of decimal places* as the least precise operand used in the calculation. The idea is that you cannot add to or subtract from something not known.
3. For multiplication and division, the answer contains the *same number of significant figures* as the least precise operand used in the calculation.
4. For logarithms, only those numbers to the right of the decimal place of the operand count as significant.

Such a set of rules constitute what is called a *significance arithmetic*.

Now, these rules should not be thought of as being perfectly reliable. Rather, they work as rules of thumb. One might be surprised that there are, well into the 20th century, many publications debating how significant digits should be analyzed and understood. This is because for any set of such rules based on significant digits it would be relatively straightforward to generate problematic cases. Thus, we see that as an attempt to provide context-independent syntactic rules meant to support management of uncertainty and its propagation, significance arithmetic has limitations. More refined mathematical methods of assessing error and uncertainty propagation in order to properly assess accuracy in a more robust way include sensitivity analysis and perturbation theory.

ACTOR–NETWORK THEORY

Actor–network theory (ANT) developed within the wider interdisciplinary field of science and technology studies (STS), and more specifically, out of debates within the sociology of scientific knowledge (SSK). SSK, in a series of case studies of scientific controversies, demonstrated that the acquisition of scientific knowledge could not be fully explained by its logic, method, or normative institutions. Taking the work of Thomas Kuhn (1922–1996) as a starting point, SSK demonstrated that the very content of scientific knowledge, including mathematics, was socially constructed. As Bruno Latour (1947–) most explicitly argued, however, SSK inadvertently replaced the natural determinism of the philosophy of science with a social determinism that was no more tenable. In addressing this criticism, ANT’s seminal case studies such as Latour’s *The Pasteurization of France* and Michel Callon’s

“Some Elements of a Sociology of Translation” followed the process of *heterogeneous engineering* by which technoscientific objects and truths were assembled and made durable through networks of human and nonhuman actors. Thus, ANT extended SSK’s symmetry principle, which held that the same types of causes should be used to explain both true and false beliefs, to a *generalized symmetry* that treated humans and nonhumans as actors with agency. Though the exact construal of nonhuman agency within ANT remains subject to debate, largely around whether to preserve intentionality as an analytically distinct feature of human action, ANT immediately gained attention as an approach to studying how *the social* is continuously enacted as relational networks of humans and nonhumans. In ANT’s subsequent articulations as a general framework for studying social order, three of its concepts, *heterogeneity*, *material relationality*, and *punctualization*, initiate a radical reconceptualization of agency, social action, and society itself. This entry addresses each concept, in turn, as well as its consequences for humanistic social theory.

ANT insists that social phenomena are *heterogeneously* constituted. That is, its objects of inquiry—whether scientific facts, nation-states, organizations, and so on—are made up of both human and nonhuman components. ANT emphasizes that a potentially endless array of *actants*, a term borrowed from literary theory and semiotics to designate any human or nonhuman that can accomplish action in a network, may constitute an object of interest. An aspect of ANT’s empirical concern thus lies in identifying, or *following*, the specific actants that are relevant in shaping the phenomena in question. In the case of California state formation, for example, Patrick Carroll argues that it is one of the most productive agricultural centers in the world only so long as levees, dams, irrigation, farmers, metering devices, state agents, and so on, are networked together. Heterogeneity greatly distinguishes ANT from humanist social sciences that, in this example, would overlook the relationship between state territories and their material infrastructures; that is, how the historicity of material culture shapes the state of California. Under an actor–network formulation, then, the state’s ontology is composed of heterogeneous elements rather than viewed as a single,

coherent actor that is distinct from society. So, an initial premise of ANT is that *the social* is made up of a heterogeneous collection of humans and nonhumans, though their relationality is always an empirical question.

To the heterogeneity of the social, add ANT's concern for *material relationality* and this is how ANT proposes to study the social world: not from *a priori*, binary divisions between humans/nonhumans, nature/culture, state/market, and so on, but in terms of how such phenomena are constituted in the continuous unfolding of heterogeneous relations. This second actor–network concept argues that entities have no essential reality apart from the web of relations in which they are produced. In other words, social phenomena are generated by human and nonhuman actor–networks and it is the relationality between heterogeneous elements that ANT's case studies pursue. This concern for relationality orients ANT toward the *way things are*, the ontological character of the heterogeneous actor–networks through which the world is made. ANT argues that what gives objects, forms of knowledge, and other social phenomena their meaning, stability, or power, must be examined in terms of how their *bits and pieces* are held together.

In the decades-old project of damming the Mississippi River, for example, an effective levee-building science develops in relation to the resistance of the river itself. Andrew Pickering captures this relational process as a *dance of agency* between engineers who build dams, a river that resists their control, and the subsequent redesign of their materials. The result is an engineering science that has become increasingly more attuned to the sedimentary composition and currents of the river. ANT case studies emphasize this always contingent, never final, way in which humans and nonhumans form more durable wholes through complex material relations. In this sense, ANT shares an emphasis on the unfolding and processual dimensions of the social world characteristic of poststructural, ethnomethodological, and pragmatist philosophies.

When taken together, heterogeneity and material relationality are significant both for the empirical study of scientific practice as well as for ANT's theory of social action. With respect to the former, ANT suggests that the work of technoscientists is not simply to follow a method, conduct experiments, and reveal the *truth* about the natural

world. Rather, technoscience is a complex and strategic practice in which the diverse materials encountered must be *assembled* into a durable, material network that can overcome unforeseen obstacles. For example, Bruno Latour's seminal case study rejected the familiar story that attributes Louis Pasteur's success to his genius mind. Instead, Latour pointed to Pasteur's technoscientific practice, the material arrangement of a heterogeneous actor–network composed of laboratories, domesticated bacteria, statistics, notebooks, microscopes, and more, as the explanation for his triumph. Pasteur's success, in other words, is an effect of organizing these heterogeneous components into a stable, material arrangement. Thus, in ANT's reformulation of social action, it was not Pasteur's rational mind that distinguished him from other technoscientists, but the collective strength of the heterogeneous actants he *assembled* as a network. This insight further supports the STS thesis that science is a social and cultural activity, and in a final move, further reconceptualizes social action.

The third concept, *punctualization*, refers to the process by which a heterogeneous network stands as a singular and coherent object or actor. It suggests that when *Pasteur-the-great-researcher* is evoked as a scientific hero it is as an effect of his heterogeneous network. Crucially, punctualization entails an oscillation between powerful individuals or objects and the contingent, network-building practices through which they become recognizable as such. The concept can thus be viewed as an alternative to human-centered histories and philosophies of science that tend to *black box* the process of knowledge production; that is, attribute knowledge itself to the brilliance of a solitary individual. As ANT instead directs empirical attention to precisely the activities through which a matter of fact is successfully constructed, it explains Pasteur's success as a heterogeneous and collective achievement, an effect of the associations of multiple heterogeneous actants. Under an actor–network formulation, Pasteur cannot become a brilliant technoscientist of eventual world renown apart from a durable network. Still more radically, Pasteur's achievement *is* the collective achievement of a heterogeneous actor–network for which he, when evoked as a singular individual, becomes a *spokesperson*.

In conclusion, ANT argues that agency, social action, and society itself are empirically complex and in need of explanation. Whereas humanist social sciences tend to privilege a social world made up of intentional, human actors and defined by boundaries such as state/society, nature/culture, and social/scientific, ANT proposes an ontology in which nonhumans and humans are analytically symmetrical in collective assemblages. It is these collective assemblages, in their complex and material relationality, that ought to be explored. ANT's concepts of heterogeneity, material relationality, and punctualization, lead to a *distributed* conception of social action concerned with a multiplicity of human and nonhuman actants. Such a thesis not only moves ANT closer to what feminist STS has considered *post-humanism*, it also orients its analytic tools to the ontological complexity of action in the world.

AD HOC HYPOTHESIS

The topic of this entry, the ad hoc hypothesis, is a small and recent footnote in a long tradition of debating how best to determine scientific truth.

On the surface, the concept is straightforward: a hypothesis is formed *ad hoc*, that is, in response to a particular situation instead of in anticipation of a general application. A host of validity issues are prompted by the introduction of an explanation ad hoc: validity of the theory, of the investigation, of the findings, and of the generalizations that may follow. These issues are the context in which the term must be understood, beginning with the fact that it is usually associated with pseudoscience, that is, conclusions which cannot be verified independently. That said, it is important to recognize a new context in which ad hoc hypotheses figure: belief revision within computer programming for artificial intelligence.

The term itself has prompted great debate concerning its definition, its purpose, and its value. Let us first consider the term *ad hoc*, a Latin phrase meaning *for this*, which is used in reference to something that is *one-off*, that is, not an established and predictable routine, but formed for a specific and short-term purpose. An ad hoc committee functions as a task force with a brief to address one issue, and then it is disbanded once the issue is addressed. The colonial militias were ad hoc because they formed in response to an immediate threat after which the soldiers reverted to their chosen occupations. In contrast, a standing committee or a standing army will have well-defined continuous roles in relation to the agencies they serve, and their members develop more professional expertise, whereas ad hoc groups operate on the common sense and skills of the average agency member. This adds to the more casual association attached to *ad hoc hypotheses*, which are also considered less rigorously developed and less valuable. An ad hoc hypothesis is produced to account for anomalies that are inconsistent with the original hypothesis.

Hypotheses are propositions of general truth, that is, a prediction of an outcome that will naturally occur based on the logic of a theory or belief. These statements are formal interpretations of the hunches and guesses that prompt researchers to investigate phenomena. Hypotheses are used to limit the scope of the investigation that is intended to test the validity of the theory prompting the research question. If the findings are inconsistent with the predictions of the theory, the theory itself is then in doubt. The value of a theory lies in its

capacity to explain naturally occurring phenomena and to help people predict and perhaps control future events. This reasoning is based on a positivist orientation to reality, meaning that the world is understood to be fairly stable and, given enough rigorous observation, its patterns can be recognized with some confidence and in turn used with confidence in similar situations. At issue is the presence of anomalies that are inconsistent with the theorized expectations, and whether they should be used to discard the theory or inform the theory. Empirical investigations are designed to test hypotheses in a systematic way so that others can replicate the procedure and thereby test the validity of the findings. Adding weight to this debate is the pride of integrity that prompts many researchers to distance themselves from practices inconsistent with their epistemological orientation and even to disparage those who appear to compromise the quality of rigor they seek.

It is safe to say that there is a keen competition among academics to claim authority. A theory is considered less robust if it cannot withstand general application without special adjustments to different circumstances. Whether termed ad hoc hypotheses or rival hypotheses or counterarguments, statements are considered fallacies if they are based on factors that cannot be tested, such as paranormal activity, or *fate*, or superstition. They may be dismissed as simply unhelpful because they distract from the task at hand or may be found unattractive because they disregard the elegance of a simple equation. They rarely add persuasive plausibility. As found in the political arena, ad hoc explanations are called *spin control* and are associated with a cynical manipulation of language to camouflage the failure of the findings to be self-evident. Within a peer review of an investigator's report, there will be keen criticism if the discussion introduces theory that was not established in the literature review justifying the research hypothesis. There is instead a convention of intellectual humility: to identify future research trajectories given the limitations of the study.

In the larger context of advancing scientific knowledge, however, the practice can be viewed as developmental in the professional researcher. The rigidity of a novice's insistence on the absolutes of binary opposites gives way to the flexibility of an expert who can tolerate ambiguity, paradox, and

multiple explanations in the process of evaluating the merits of a theory. The naïve and inexperienced are motivated to defend a preconceived notion, while the more experienced will consider the pattern of empirical evidence. These are in fact the argumentational and rhetorical skills necessary for scientific discourse: generating evidence and counterarguments to establish proof and certainty. Ad hoc hypotheses are a function not of the original experimental design but of its interpretation by the investigator. The investigator may believe that this modification improves the explanation of the phenomenon, but the more traditional scientific community tends to regard this as an evasion, motivated by a desire to protect the theory in question from disputation.

The role of ad hoc hypotheses could be absorbed into the fabric of basic scientific discourse were it not for a current interest in mechanizing the executive function of decision. *Artificial intelligence* is a contemporary field attempting to program computers with all possible contingencies so that the program can actually *learn*; that is, revise its own procedures based on responses. A computer program is a series of propositions requiring the programmer to predict the nature of decisions to be made, contingent on other actions. The algorithm by which the program proceeds through these decisions is of course crucial to the outcome, for a simple reversal of steps can result in a significant change. *Belief revision* in this context does not mean a change in philosophical conviction about reality or morality, but a change in technological procedures that are, from the standpoint of the machine, the way things are. These are fundamental issues for the organization of information within all fields, so a belief revision theory launched a wide-ranging field of research. This theory is found in the Alchourrón, Gärdenfors and Makinson (AGM) model, a formal framework for analyzing ways to change beliefs in the context of computer programming. The three researchers collaborated from different fields to propose it, illustrating the multidisciplinary interest in this logic. Complex mathematical formulae are the currency of this discourse, akin to setting up an intricate series of dominoes in readiness for a simple action to trigger a long sequence of response. This enterprise assumes a closed system of variables; that is, it operates within a set of propositions, but as

databases accumulate, they must be updated, leading to an important concept of database priorities within truth maintenance systems. They are also deterministic in that given a set of beliefs responding to some input, the resulting belief set is well anticipated. A combination of operators may be used as an indeterministic operator that allow more than one admissible outcome. Ad hoc hypotheses are thus a mainstay of the dynamic process.

Ad hoc hypotheses highlight the epistemological distinctions between belief and knowledge, between intuition and theory, and between deductive and inductive approaches to problem-solving. Opinions about what ad hoc hypotheses are, and their value, reflect one's orientation to identifying truth based on observed phenomena, on principles derived from an accepted theory; for example, syllogisms associated with Aristotle, or on authoritative conclusions such as those demonstrated in Socratic dialogues, which used hypothetical situations for support of interpreting ideals. Modern rationalism follows René Descartes' four steps of scientific thinking: skepticism (that nothing is true until proven so), reductionism (divide concepts into much smaller entities that are more easily observed), organization (ordering knowledge from simple to complex), and generalization (refining a theory to eliminate omissions and contradictions). Francis Bacon argued that theory must be built from the ground up by first accumulating a large sample of data, then proposing some preliminary axioms or predictable patterns, and finally generating a theory that would explain all the phenomena.

ANALYSIS

According to the prevailing definition, analysis is a process that involves breaking something up into simpler or component parts. Indeed, the word *analysis* derives from the Greek *ana* for up and *lysis* for loosening or separation. But analysis can also be conceived as the search to determine prior principles, beginning from what is known—a conception with roots in ancient geometry and with purchase in academic philosophy. Analysis can be contrasted with its converse, synthesis, which is the process of joining parts or elements together to create a more unified result. Both synthesis and analysis are directed toward the ends of elucidation; through analysis, that which is being analyzed becomes better or more fully understood.

Analysis is a fundamental mode of inquiry and is applicable without restriction; one can conceivably analyze anything. As a result, it occurs throughout lay and specialized academic contexts. In their daily lives, people regularly engage in analysis, analyzing the texts they read or watch, the events they attend, the words, deeds, and behaviors of other people, and so on, discerning component parts of larger wholes. Similarly, scholars employ analysis across a wide range of academic contexts, including the sciences, social sciences, arts, business fields, and in math and the humanities, where it is a basic building block of intellectual pursuit. Scholarly analysis is generally distinguished from lay analysis by a greater degree of rigor and formalization, though the extent to which it is either depends on the particular discipline and method.

As a decompositional process, analysis includes both descriptive and pattern-seeking activities. As descriptive, analysis involves identifying the parts of a whole and providing an account of the relevant features of those parts, in some greater or lesser degree of detail. As a result, it is closely tied

to observation; and the observation that drives analysis can involve any of the senses: visual, auditory, gustatory, tactile, or olfactory. Moreover, in order to facilitate analysis or, in some cases, even make it at all possible, one might utilize instruments to augment one or more of the senses. The analysis of physical entities or qualities, for examples, often involves the use of instruments or tools. But perhaps more often than being purely descriptive, analysis also entails the search for patterns. Breaking a larger and more complex whole into smaller and more elementary parts brings the interactions between those parts into focus. And in analyzing, one classifies and groups, identifying relationships and drawing conclusions about them.

Analysis is a comprehensive term that refers to a highly generalized activity, which can be actualized in innumerable different ways. For example, analysis can proceed at any level of abstraction. While a biologist might probe a tangible organism in order to analyze its concrete parts, philosophers use conceptual analysis to examine thoroughly abstract concepts like *truth* and *knowledge*. Levels of granularity also vary widely; coarse-grained macro-analyses assess relatively large-scale components, while fine-grained micro-analyses consider relatively small ones. One can even analyze analyses, as is the case in a meta-analysis. Indeed, there are innumerable different approaches and/or specific formalized methods one can employ in order to analyze a target of interest, some of which are outlined in the subsequent sections of this entry.

Analysis is an inherently interpretive activity. In the processes of analyzing, one makes decisions about where to direct attention, about what constitute the meaningful parts of a whole, and construes the existence of relationships and patterns. And while such judgments are sometimes relatively clear-cut, they can also be uncertain and arguable. In the act of breaking something down into its component parts, therefore, we explain how to understand it and make a case for what it means. We render it otherwise. As a result, the terms *analysis* and *interpretation* are sometimes used synonymously. For example, an analysis of a poem might also be described as an interpretation of it. Interpretation, however, does not have the decompositional emphasis that analysis does.

Moreover, interpretation often tackles questions of meaning that fall outside of the purview of analysis. Similarly, analysis differs from criticism, another related intellectual pursuit, in that it is not in essence evaluative.

An analysis is not only the act of breaking something down into component parts but also the communicated record or result of so doing. The form of that resultant analysis depends on the type of analysis one has done and the type of context in which one has performed it.

Deductive Approaches

In deductive approaches to analysis, an existing hypothesis, theoretical model, or conceptual framework guides the descriptive and pattern-seeking activities of analysis. Therefore, the hypothesis, theory, or framework directs attention, determining to some extent the parts, patterns, and relationships delineated. As such, they can be characterized as offering a perspectival lens. For example, in a hypothetico-deductive experimental paradigm, one analyzes data in relation to a preidentified hypothesis to determine whether or not it supports that hypothesis. Similarly, a deductive analysis of a dream guided by Freudianism will focus on features specified by or emphasized in Sigmund Freud's psychoanalytic theory, such as repressed memories and unconscious desires.

Within disciplines, certain conceptual frameworks tend to predominate, becoming frequently engaged as analytic tools. In the humanities and social sciences, for example, psychoanalysis, Marxism, feminist theory, structuralism, critical theory, phenomenology, and deconstruction have all been commonly employed toward the ends of deductive analysis. Those employing these and other models in a deductive fashion must guard against confirmation bias, or the tendency to only look for/see that which confirms an existing hypothesis, overlooking those features that do not fit within its parameters. Similarly, deductive approaches are vulnerable to what is sometimes called *cooker-cutter criticism*, whereby a theoretical framework so strongly and narrowly governs analysis that it becomes a rote and mechanical application of theory with predetermined and not particularly insightful results.

Although an explicitly acknowledged and articulated theoretical framework drives some analyses, the principles that guide analysis in a deductive fashion are sometimes implicit. This is particularly true in lay contexts, where neither theoretical frameworks nor the process of analysis are typically formalized, but also occurs in scholarly contexts as well. Moreover, folk theories sometimes deductively underlie scholarly analysis in a covert fashion. The mobilization of implicit theoretical frameworks can be problematic given that the premises by which the analysis is guided are not articulated and may not be apparent to the person doing the analysis and/or the person encountering the results of the analysis, making them unavailable for discussion or critique.

Inductive Approaches

In inductive analysis, inquiry begins with the analysandum itself; one works with and from the object of interest in order to discern its meaningful parts and draw conclusions about the relationships between those parts. That is, the *breaking down* of this form of analysis involves a *building up* from particulars as one moves from specific features to more general conclusions about parts and patterns. An example of a commonly employed inductive method of analysis in the humanities is close textual analysis, which involves paying scrupulous attention to the details of a selected work or works, from the use of commas to the overarching organization, to identify patterns within that work and/or among works.

However, though theory does not drive an inductive analysis, it must inevitably be guided by something, which often includes intuition or past experience with other texts. This raises the question of the extent to which any analysis can in fact shelve theory, and whether inductive approaches are in fact inevitably theory-laden, even if that theory is of the informal and implicit kind that comprises intuition and develops out of experience. Moreover, philosophical debates about and psychological investigations into the theory-ladenness of observation are clearly applicable to analysis given its reliance on observation.

The human impulse to see and seek patterns and connections not only results in a general affinity for analysis, but also a propensity to see

patterns and perceive connections where there are none. This tendency underlies many superstitious and supernatural beliefs and is responsible for much of what is termed *magical thinking*, but it is also a tendency with implications for scholarly analysis. *Overreading* or *overinterpretation* are terms sometimes used to describe overly aggressive acts of analysis in which patterns are read into a text rather than being found there; and this problematic analytic misstep can be found in all sorts of analyses, from the poetic to the radiographic.

While deduction and induction are distinguishable orientations toward analysis, in practice the two often co-occur. They do so in a compelling way in the *grounded theory method*, a formalized methodology developed in the social sciences by which one self-consciously and systematically puts inductive analysis toward the ends of theory development. In using analysis to arrive at theory, one reverses the typical or traditional pattern by which theory precedes analysis. It is an iterative process in that one repeatedly moves back and forth between data and analysis, and between inductive and deductive modes of thought, becoming increasingly abstract and theoretical as the process unfolds.

Quantitative Analysis

Quantitative analysis is the analysis of that which has been quantified; that is, calculated, counted, or measured. And in practice, it can take many different forms. Perhaps the simplest type of quantitative analysis is the discernment of relative quantities. A quantitative chemical analysis of this type, for instance, might determine the amounts of the various component parts of a more complex chemical. But quantitative analysis often moves beyond the relatively straightforward assessment of amounts, to discern patterns and relationships, which is a way of making numerical data meaningful and/or useful. Quantitative analysis can also be put toward the ends of prediction. In predictive analysis, one looks at what has happened in the past and identifies patterns in order to predict future events, as in analyzing voting behavior in previous election cycles to predict outcomes in upcoming ones.

Statistical methods are mathematical tools for seeking out and delineating the patterns in a

quantified subject of analysis. Indeed, statistics, a branch of mathematics, is the science of quantitative analysis. Statistics can be applied in a deductive fashion, as in confirmatory data analysis, whereby one identifies a hypothesis and employs statistical analysis in order to test it. Or one can use statistics in a more inductive fashion, applying them to a set of data in order to see what patterns emerge, a type of exploratory data analysis. There are two main branches of statistics, descriptive and inferential. *Descriptive statistics* are methods for characterizing the features of a given set of data; these include measures of central tendency (i.e., mean, median, and mode) and spread (i.e., range, variance, and deviation). *Inferential statistics* are methods for using a sample in order to identify the parts, patterns, and relationships of a larger population; in doing so, the quality of the sampling process is key. *Regression analysis* also deserves mention as a set of powerful statistical processes for examining the relationships between variables, often independent and dependent ones.

In some quantitative studies, particularly those in the social sciences, coding is an important initial step in the analysis process. It is the procedure by which one applies shorthand labels to data items, such as parts of interview transcripts or field notes; in doing so, one not only categorizes them and enables them to be more readily sorted, but also makes them countable and thereby amenable to analysis via quantitative techniques. For example, content analysis, a technique for analyzing communicative acts, often employs coding toward the ends of quantification. When coding, one must decide on the unit of analysis (e.g., words, paragraphs, parts of images, entire photographs) and whether to use predetermined codes or to derive codes during the course of coding. The process of coding data does some analytical work in that it discerns recurring features. It also facilitates subsequent *higher-level* analysis. The reliability of the coding process is an important consideration, and studies often consider *intra-coder reliability*, or the consistency with which a given person codes the data, and to enhance reliability, some studies employ multiple coders, and consider *inter-coder reliability*, or the extent to which they agree with each other.

Visualization is also an integral part of quantitative analysis. The results of quantitative analysis

are often effectively presented in visual form, which can incisively convey patterns and relationships between component parts. Tables and graphs, frequency distributions, bar charts, scatterplots, and histograms are all commonly used to present the results of a quantitative analysis. Moreover, data visualization is itself considered a method of quantitative analysis and a branch of descriptive statistics. As a method of analysis, we can consider the process of visualization itself as that which discerns meaningful components and their relationships.

As a result of advances in computing, quantitative analysis has become not only more large-scale and sophisticated, but also increasingly democratized. While the computing power necessary to do complex statistical analysis used to be in the hands of only a few, it is now much more widely available. Moreover, there is now unprecedented access to vast data sets, such as those generated via new media, offering opportunities large-scale quantitative analysis with considerable potential across academic disciplines and for commercial purposes. In professional fields, the word *analytics* is often used to refer to the science of data analysis.

Qualitative Analysis

Qualitative analysis is the analysis of that which has not been (and perhaps cannot be) measured or quantified. It focuses on qualities and features rather than amounts. For instance, a qualitative chemical analysis might detail the characteristics of the component parts of a more complex compound. As with quantitative analysis, qualitative analysis can proceed inductively or deductively; that is, one can take the detailed particulars of the analysandum as the analytic starting point or can proceed on the basis of a theoretical framework.

While the phrase *qualitative analysis* might well be used to identify a wide range of analytic inquiry, it is generally associated with a research paradigm in social science fields that emerged during the 20th century to develop and systematize qualitative methods as legitimate alternatives to positivistic and quantitative ones. As a result, not all of those who engage in analysis that could certainly be described as qualitative would necessarily use that phrase to describe

their work, particularly those who work in the humanities. For example, philosophy's tradition of conceptual analysis, which is solidified in the branch of philosophy known as *analytic philosophy*, is certainly not quantitative, but philosophers would not tend to identify it under the banners of *qualitative analysis* and *qualitative research*.

In the social sciences, qualitative analysis tends to be rather systematized and is often part of a research process with parallels to scientific research. For example, the qualitative data are often systematically generated or collected for the purposes of analysis; this is in contrast to the analysis of something preexisting and simply selected for study, as in a rhetorical analysis of an influential speech or the art historian's analysis of a famous painting. Qualitative researchers in the social sciences might conduct interviews, run focus groups, and engage in participant observation, analyzing the transcripts or notes that result from these activities. These textual data are also often coded, a process that is not only an instrument of quantification but is can be a means of sorting data and thereby facilitating qualitative analysis. Some of the specific approaches to qualitative analysis that are widely used in the social sciences include narrative analysis, discourse analysis, phenomenological analysis, and grounded theory.

Qualitative and quantitative analysis can be complementary ways of discerning the parts and patterns of a subject of interest, and many research projects, such as mixed-methods studies, use both. Moreover, social scientists sometimes use qualitative analysis in order to engage in initial exploration of a subject, followed by quantitative analysis to test hypotheses derived from those exploratory qualitative endeavors.

Critiques of Analysis

Alongside the widespread embrace of analysis as fundamental mode of intellectual engagement exists a strain of skepticism regarding its power to elucidate. The so-called *paradox of analysis*, associated with C. H. Langford and G. E. Moore, is, essentially, the idea that to give a correct analysis of a concept, one already has to know and be able to identify its component parts. For instance,

Moore provides the example of analyzing the concept of brother into male and sibling, something that requires already knowing what a brother is. The analysis is trivial and does not provide any new insights. As a result, it follows that it is impossible for an analysis both to be correct and to inform us of something we do not already know. And although debates regarding paradox of analysis (which include attempts to resolve it) occur specifically in relation to philosophical conceptual analysis, the paradox has relevance to analysis more broadly considered.

Others express concern regarding analysis's essential reductiveness; by definition, analysis involves breaking things down, distilling the elementary parts from the more complex whole. Philosophers such as Georg Wilhelm Friedrich Hegel and Friedrich Schiller have pointed toward the reductive dimension of analysis. Pierre Teilhard de Chardin once described analysis as "that marvelous instrument of scientific research to which we owe all our advances but which, breaking down synthesis after synthesis, allows one soul after another to escape, leaving us confronted with a pile of dismantled machinery, and evanescent particles" (1959, p. 283). That is, the elucidation of analytic dismantlement is not without its losses.

APPLICABILITY OF MATHEMATICS IN SCIENCE

Our understanding of nature, our explanations of natural phenomena, crucially depend on the use and interpretation of mathematics in scientific practice. Mathematics provides a common language for the empirical (i.e., the natural and social) sciences, and through its tools, we get successful predictions and empirical confirmations that are about the entities and the phenomena of these sciences. When this happens, we say that mathematics successfully applies in science. But the success of mathematics in science prompts the following question: How is it possible for the abstract entities of mathematics (numbers, equations, integrals, etc.) to say something interesting about phenomena and entities, as for instance nuclear reactions and proteins, which are studied by the empirical sciences and have a completely different nature? The issue is philosophical, and the research topic associated to it is known as the *Applicability of Mathematics in Science*. Following a short introduction to the topic, this entry offers an overview of some accounts that have been proposed to tackle the philosophical issue. It also identifies some connections that have been established between the study of the applicability of mathematics in science and other debates in philosophy of science and philosophy of mathematics.

The Philosophical Challenge

When will Mars be closest to Earth? What is the distance covered by a falling body in a given time under the force of gravity? Given a protein with a specific amino acid sequence, what will its three-dimensional structure be like? What is the average

number of predators in a particular ecosystem? How can we maximize profit in a market economy with production constraints? Although these questions involve entities (planets, falling bodies, proteins, predators, production constraints) and empirical sciences (physics, computational biology, ecology, economics) that are quite different from each other, there is a common path to answer them: Do the math! Surprisingly, mathematics works. This, of course, does not mean that mathematics always works when it is used, or *applied*, in the empirical sciences. Nevertheless, in many cases, mathematics provides a correct, empirically accurate, answer to our original question about planets, proteins, predators, and so on. Why should we be surprised about such effectiveness, or successful applicability, of mathematics? The issue is philosophical: Mathematical entities are generally regarded as abstract because they do not causally interact with anything (e.g., a number cannot break a glass) and have no spatiotemporal location (e.g., a number cannot be found in a certain place at a certain time); therefore, it is quite surprising that they can properly inform us on the behavior and properties of entities like planets or proteins, which are causally active and are located in space and time. Even more surprisingly, sometimes the mathematics that is successfully used in science is not developed from scratch to study an empirical problem, but it has been developed within a purely mathematical framework before being used with success in a specific context of application (the mathematics of group theory, for instance, was developed long before its introduction into quantum physics in the late 1920s).

It is exactly this particular feature of mathematics, namely that of being applicable with success outside its boundaries, that allows scientists to make extraordinary progress in the understanding of nature. And the main goal of philosophers of science and mathematics working on the applicability of mathematics in science is to investigate such features and account for the (successful) application of mathematics in science.

Facing the Challenge

The applicability of mathematics has a long-standing philosophical pedigree. Indeed, the first reflections on the successful use of mathematics to

understand the world can be traced back at least to early Pythagoreanism (sixth through fourth centuries B.C.E.) and to the investigation of harmonic intervals in terms of arithmetic. In classical Greece, harmonics was the science that investigated the arrangements of pitched sounds that form the basis of musical melody and the principles that govern them. What the early Pythagoreans discovered is that some differences in pitch between two sounds, or intervals, were expressible by numerical ratios (e.g., they found that the three basic intervals of octave, fifth, and fourth were expressible as the numerical ratios 2:1, 3:2, and 4:3). Thus, an arithmetical ratio could be successfully used to represent a perceptible phenomenon. To account for this fact, they proposed a metaphysical system wherein everything is a number understood via discrete representations. In this “all is number” doctrine, which is illustrated in Aristotle’s *Metaphysics*, the world consists of corporeal numbers, or units, and mathematics applies to the world because the world has such mathematical structure.

Although the Pythagoreans pioneered the study of our topic, later attempts to explain the applicability of mathematics in science departed from their view. The Greek philosophers Plato (ca. 429–347 B.C.E.) and Aristotle (384–322 B.C.E.), for instance, developed different approaches to the applicability issue.

For Plato, the physical world and all of its constituents are imperfect copies, approximations, of special abstract entities called *Forms*. The world and its constituents derive from Forms, which include—but are not limited to—mathematical entities and properties. For instance, a drawn square belongs to the material world, but it is an imperfect, approximate copy of the square as such, whose angles are exactly 90° and whose sides are perfectly straight. Because all copies are dependent on ideal Forms, the physical world is dependent on Forms. Therefore, for Plato, mathematics is applicable to the physical world because it is a science of the ideal Forms from which the physical world is derived.

Aristotle disagreed with Plato about the nature of mathematical objects. While for Plato material objects are imperfect copies of ideal forms, and the former are derived from the latter, Aristotle maintains that mathematical objects are obtained

from physical objects through a process of *abstraction*: We consider a physical object with respect to some of its attributes, next we take them out, and finally we create a new (abstract) object consisting in that object in only those respects. The result of this process is an object in its own right. The *snub-nose* is Aristotle’s favorite example: If we consider a snub nose, the quality of snubness comes from sense perceptions and is concavity in the physical object *nose*; the mathematical quality of concavity, on the other hand, is obtained by removing all the attributes of the nose with the exception of its shape. Thus, according to Aristotle, mathematics studies the objects formed by abstraction but not the material objects on which the abstraction process operates. And this view provides an account of how mathematics applies to the world.

The philosophical standpoints proposed by Plato and Aristotle were very influential until the early modern period. The Italian astronomer, engineer, and physicist Galileo Galilei (1564–1642), for instance, echoes both views in *The Assayer* (1623) and in the *Dialogue Concerning the Two Chief World Systems* (1632). But the mathematization of physics that took place during the 17th century, largely influenced by the publication of Isaac Newton’s *Principia* (1687), marked a radical departure from the dominant tradition of a natural philosophy that aimed to give qualitative explanations of natural phenomena. In the new conceptual framework that arose, where the objects of physics also included objects that were themselves mathematical (e.g., Newton’s concept of force), philosophical analysis such as those offered by the Pythagoreans, Plato, and Aristotle were insufficient to account for the applicability of mathematics. Therefore, philosophers had to elaborate new strategies to explain the applicability of mathematics. Immanuel Kant (1724–1804), for instance, proposed—within his transcendental idealism—the idea that it is the constitution of the subject that makes it necessary to describe the world mathematically. In his *System of Logic* (1843), John Stuart Mill argued that mathematics is itself empirical since mathematical truths are generalizations derived from experience. Other philosophical standpoints were offered. Nevertheless, as happened with the accounts proposed by the ancient Greeks, these conceptions had to be revised or even abandoned in light of new, unexpected interactions between

mathematics and science (e.g., the application of non-Euclidean geometry in Albert Einstein's theory of general relativity undermined Kant's view, and particularly his conception of the synthetic *a priori* character of geometry).

Successful interactions between mathematics and the empirical sciences have been growing massively since the first half of the 20th century. This phenomenon captured the attention of many scientists, as for instance the Nobel laureates in physics Eugene Wigner and Richard Feynman, and gave a new impetus to the philosophical study of the applicability of mathematics. Several analyses were developed but, in general, we can identify three main strategies that have been adopted to address the applicability issue: (1) a logicist approach, (2) an attempt to explain the applicability of mathematics by focusing on the way in which mathematical concepts are introduced in scientific theory-building, and (3) a strategy that elaborates on the idea that the applicability of mathematics can be explained in terms of some correspondences that can be established between a mathematical domain and an empirical domain. Let us consider the three strategies in turn:

1. In philosophy of mathematics, *logicism* is the view that mathematics, or part of it, can be reduced to logic. This view was developed by the philosopher Gottlob Frege at the end of the 19th century. According to the logicist standpoint, mathematics can be applied to the description of the world because it contains only logical concepts, which can be applied to any possible domain of objects. Although Frege's attempt to demonstrate logicism was undermined (because of an inconsistency that was found in his formal logical system), by the mid-1960s, some philosophers of mathematics tried to revive some of the core ideas of logicism and set in motion a philosophical movement that has been called *neologicism*. Neologicists defend *Frege's constraint* (also known as *application constraint*), a principle that was one of the main tenets of Frege's logicism and which requires that the empirical applications of a mathematical theory (or class of numbers) must be built directly into the formal characterization of the mathematical theory (or class of numbers). Thus, although in a renewed form, neologicist projects that meet Frege's constraint continue to offer an account of the applicability of mathematics by demanding that an explanation of applicability be provided inside mathematics, by mathematical definitions.
2. A second strategy, which was largely inspired by the emergence in the 1960s of a tradition in philosophy of mathematics that was concerned with the dynamics of mathematical discovery and the historical development of mathematics, focuses on the way in which the introduction of mathematical concepts is influenced by theory-building in science. Philosophers who follow this route draw on analyses of the historical development of mathematics and present case studies in which mathematics and science simultaneously develop in a theory-building context. By emphasizing the interplay between mathematics and other kinds of practices that we find in theory-building (e.g., the practice of identifying analogies between different scientific theories), they argue that the effectiveness of mathematics in science is no longer surprising when we see that (and how) much mathematics is brought into being by the need to model one or more aspects of the world (an example of such an analysis can be found in the paper "Solving Wigner's mystery," written by the historian of mathematics and logic Ivor Grattan-Guinness and published in 2008).
3. A third strategy, which has been the most influential since the first decade of the 21st century, gives an explanation of the applicability of mathematics in terms of mappings that are established between mathematics and the empirical systems we want to study. These mappings are mathematical and include not only isomorphisms but also other kinds of mathematical mappings like homomorphisms, epimorphisms, and monomorphisms. Mappings ensure that some crucial features of the empirical system are mirrored in the mathematical model used to study that system. Such an approach has been called *the mapping account of applied mathematics*. According to this view, the applicability of mathematics is fully accounted for by appreciating the relevant structural similarities between the empirical system under study and the mathematics used in the investigation of that system.

There have been many attempts to implement the mapping account, but the most discussed has been that proposed by Otávio Bueno and Mark Colyvan in their 2011 paper “An inferential conception of the application of mathematics.” Bueno and Colyvan retain the basic idea behind the mapping account (i.e., the idea that the successful application of mathematics amounts to establishing a suitable mapping between mathematics and an empirical setup) and propose a view of applicability, called *the inferential conception*, in terms of a three-step process: (a) immersion (a correspondence between mathematics and the empirical setup is established via a suitable mapping), (b) derivation (some consequences are generated from the mathematical formalism), and (c) interpretation (the mathematical consequences obtained in the derivation step are interpreted in terms of the initial empirical setup, via a mapping that does not necessarily coincide with the mapping used in the immersion step).

Connections With Other Debates

The growth in successful interactions between mathematics and science played a motivating role in advancing analysis of the applicability issue. Nevertheless, philosophical interest in the applicability of mathematics was also prompted by the investigation of three topics that have become increasingly central to the agenda of philosophers of science and mathematics since the 1970s: mathematical modeling in science, mathematical explanation in science, and indispensability argument(s) for mathematical Platonism.

Mathematical Modeling in Science

Mathematical models are used in science to represent and study a selected part or aspect of the world, which is named the (model’s) *target system*. For instance, the so-called Lotka–Volterra model, developed by the mathematicians Alfred Lotka and Vito Volterra in the 1920s and consisting in a pair of differential equations, is used in population ecology to represent a system of two interacting species (a predator and a prey) and study its dynamics. Sometimes, a mathematical model can also be used to represent and study two different target systems (e.g., the same equation can be used

to represent and study a swinging pendulum and an oscillating electric circuit). Furthermore, the target system represented in the model is usually an *idealized* version of the real system, namely a simplified or distorted version of it. For instance, when we study a swinging pendulum, we usually assume that the pendulum bob is a point mass and that the string is massless. With these idealizations in place, the target system becomes more tractable from a mathematical point of view.

It is therefore easy to see how the investigation of the applicability of mathematics is closely connected to discussions of mathematical modeling in science: An account of how a mathematical model can be used to represent and study a target system prompts an explanation of how mathematics is applied with success to the physical world (or, if we consider the case of idealizations, an explanation of how mathematics is applied with success to those idealizations that are about the physical world).

Mathematical Explanation in Science

To explain something is to give the reason why that something happens (rather than a mere description of it). For instance, to explain a solar eclipse is to give an answer to the question “Why did the solar eclipse occur?” rather than a simple description of the eclipse phenomenon. Explanations are therefore particularly important in science, which investigates the reasons why empirical phenomena (such as the solar eclipse) occur.

Many explanations in science appeal to causes. These *causal explanations* provide information about what caused the thing that we want to explain (e.g., a solar eclipse is caused by the interposition of the moon between the sun and the earth). Moreover, many scientists and philosophers have argued that there also exist mathematical (and therefore noncausal) explanations in science. In this kind of explanation, it is mathematics that unveils the reason why an empirical phenomenon occurs. Nevertheless, there could be no mathematical explanation of empirical phenomena if mathematics were not successfully applied in the sciences dealing with such phenomena (note that the converse of this conditional statement is not true since there may be successful applications of mathematics that are not

explanations). Therefore, articulating a plausible account of the applicability of mathematics in the empirical sciences is particularly important for those philosophers who maintain that mathematics can play an explanatory role in science.

Indispensability Argument(s) for Mathematical Platonism

Platonism in philosophy of mathematics is the view that mathematical objects exist (independently of us and our language, thought, and practices). The indispensability argument is a philosophical argument used by Platonists to defend their view and argue that there are mathematical objects. There exist several versions of the argument but, in its original formulation (which is credited to the philosophers Willard Van Orman Quine and Hilary Putnam), the argument goes as follows: Since we ought to believe in the existence of those entities that are indispensable to our best scientific theories (like electrons or black holes), and since mathematical entities are indispensable to our best scientific theories (i.e., our best scientific theories like quantum mechanics and general relativity cannot be formulated without making reference to mathematical entities), then we ought to believe in the existence of mathematical entities. In this line of argument, mathematical entities are seen to be on an epistemic par with other theoretical entities of science like electrons or black holes (and so anyone who believes in the existence of the former should also believe in the existence of the latter). Furthermore, the argument crucially presupposes that mathematics successfully applies in science. Hence, again, we see how investigations into the applicability of mathematics are linked to, and triggered by, the study of a separate topic.

Although discussing other formulations of the indispensability argument is beyond the scope of this entry, it is worth noting that there is a version of the argument that relies on the notion of mathematical explanation in science. Early presentations of such an *enhanced* (or *explanatory*) indispensability argument can be found in philosophy of mathematics before the end of the 20th century, but an explicit formulation appears in 2005 in Alan Baker's paper "Are there genuine mathematical explanations of physical phenomena?" Since, as

discussed earlier in this entry, successful applicability of mathematics is a necessary—although not sufficient—condition for mathematical explanation in science, the issue of explaining why mathematics applies with success in science also arises in the context of the enhanced indispensability argument.

ARTIFICIAL INTELLIGENCE

Artificial intelligence (AI) is loosely defined as the capacity of machines that can accomplish tasks that humans would accomplish through thinking. This definition does not say anything about AI achieving this performance in ways similar to how we humans do it, however. The term *artificial intelligence* is used with two meanings. On the one hand, it refers to (artificially) intelligent machines and the ways of making them; in this sense, AI is primarily computer science and engineering. On the other hand, AI is also a transdisciplinary field of studying these machines. AI gurus such as Herbert Simon often emphasized that studying AI involves studying the human mind, and if we get it right, we will understand both AI and the human mind better in the end. Therefore, the field of AI involves various branches of hard sciences and engineering but beyond these also biology, psychology, and philosophy. This entry introduces the types of AI and describes their origins and the ways in which the types differ from each other. Next, the entry pursues the question of what defines intelligence and whether AI machines can be said to *think*. The entry continues with a discussion of the two paradigms of AI research, *strong AI* and *weak AI*. This is followed by an examination of the nature of knowledge and learning and the differences between AI and the human mind—a distinction reinforced in concluding remarks on the importance of this essential consideration in shaping the future of humankind.

Types of AI

The term *artificial intelligence* was coined by the computer scientist and cognitive scientist John McCarthy during a 2-month workshop organized

at Dartmouth College in summer 1956. At the time, only one program (discussed below) qualified for the name, so it was the result of philosophizing about what computers should be capable of. To unpack the concept of AI, it is useful to distinguish between the different types of AI and to delineate facts from beliefs in the process. In this section, the three main types of AI, namely *symbolic reasoning systems*, *symbolic expert systems*, and *artificial neural networks* (ANNs), are examined.

Symbolic Reasoning Systems

The first *thinking machine*—that is, the first AI implementation that worked—was called the *Logic Theorist*, or *Logic Theory Machine*. It was created in 1956 by the Nobel laureate Herbert Simon, his former PhD student Allen Newell, and Cliff Shaw from the RAND Corporation. The purpose of the Logic Theorist was “[. . .] to learn how it is possible to solve difficult problems such as proving mathematical theorems, discovering scientific laws from data, playing chess, or understanding the meaning of English prose” (Newell et al., 1963, p. 109). The Logic Theory Machine gradually evolved into the even more ambitious General Problem Solver, which was supposed to extend the original scope to all areas of human problem-solving. This was the first tentative attempt at what is today called *artificial general intelligence* (AGI).

The departure point was the philosopher Thomas Hobbes’s idea from the 17th century, popularized by AI pioneer Oliver Selfridge (1926–2008), suggesting that all human problem-solving could be represented as a manipulation of symbols. If this was true, Newell and Simon speculated that computers should be able to solve real-world problems, not only arithmetic problems. They tried to achieve this by recording the steps of human problem-solving, using the *thinking aloud* technique: They asked problem solvers to note all the steps of their thinking. Newell and Simon figured that if they repeated the same in many areas of human problem-solving, they should be able to extract the general principles of reasoning, and by applying these principles and generic steps, AI should be able to work across multiple domains. The idea was a radical

departure from the optimization and operational research methods of the time, which started with a detailed model of the complete problem. The performance delivered by the Logic Theorist was astonishing; eventually, it proved 38 of the first 52 theorems in the *Principia Mathematica*, a foundational work in modern symbolic logic by Alfred North Whitehead and Bertrand Russell.

What are the facts and what are the beliefs of symbolic reasoning systems? The first problematic assumption is that all thinking can be represented as symbol manipulation; there is no convincing evidence, so it is just a belief. The second assumption is that there are general principles that apply across all areas of problem-solving; it is difficult to imagine that there are some generic steps that apply from cooking a stew to designing a car or composing music. However, even if this does sound convincing, it is a mere belief. The third assumption is that playing chess or proving theorems, which may arguably involve explicit logical steps, has anything in common with “understanding the meaning of English prose” or anything that involves the achievement of meaning. It is nothing more than a belief. The fact is that the performance of the Logic Theorist was impressive, and since then, similar AI solutions have proved many more theorems and suggested new ones. What has not happened is an AI finding a surprising or significant theorem.

Symbolic Expert Systems

Often called the “father of symbolic expert systems” is Edward Feigenbaum (b. 1936), previously Simon’s PhD student. He abandoned the general principles of reasoning to focus on narrow domains of expertise. He figured that in order to deliver performance on par with a high level of expertise, AI would need to have an internal *model*; a representation of the problem, which would be reasoned. As he began working with scientists, Feigenbaum anchored his project in experimental design in order to make testing possible. Joined by the Nobel laureate Joshua Lederberg, he decided to build a system that would induce molecular topologies from mass spectra, in order to support the Mars probe looking for life, or the precursors of life, on Mars. The project was

named DENDRAL. The input data were reliable, the calculations needed were beyond the usual but not beyond the AI capabilities of the time, and there was a chance to test the findings empirically. The DENDRAL ran for many years, involving an increasing number of experts, eventually covering a larger area than any of the individual experts did. Eventually, the program was performing on par with, and exceeding, top experts.

The DENDRAL was the first *knowledge-based expert system*. A system being *knowledge-based* refers to the internal model, called *knowledge representation*, which is stored in the form of a *knowledge base* (this can be thought of as a cleverly designed database that stores knowledge), while the term *expert system* signifies, not surprisingly, that expert knowledge was represented. The knowledge representation is obtained in the process of *knowledge acquisition*, which is a subset of the overall process of *knowledge engineering*. The facilitator who works with the experts to model their knowledge is called the *knowledge engineer*. As DENDRAL was expanded, the complexity of the knowledge base increased, eventually threatening the stability of the initial LISP (a programming language focused on linked lists) system. Therefore, Feigenbaum’s colleague Bruce G. Buchanan reprogrammed the system, establishing what became the standard for knowledge bases: the “production rules,” or hierarchically organized “if . . . then” rules.

The facts about expert systems are that Feigenbaum was meticulous in selecting a suitable problem for this type of AI: The problem was of the right size, the right level of complexity, experts were available, and there was a possibility of checking the outcome. This is still the crucial feature of expert systems today. In other words, Feigenbaum’s assumptions stood the test of time. Feigenbaum mentioned his belief in AI superintelligence, but this was not used as an assumption for developing expert systems. For many years, expert systems were *isolated*, in the sense that there was no connection and interoperability between knowledge bases; today, knowledge bases can be connected and provide input to each other. The main limit of expert systems today is *brittleness*, meaning that although expert systems deliver high performance in their narrow domains, they are

completely useless even a tiny step beyond their domain's boundary, as there is no representation of nonspecialist knowledge.

Knowledge-based expert systems dominated the AI landscape until the mid-1980s, producing a large number of successful implementations in a wide range of areas from science and manufacturing through to medical treatments.

Artificial Neural Networks

The first ANN was conceptualized in 1943 by Warren McCulloch and Walter Pitts, while the first implementation, the SNARC (Stochastic Neural Analog Reinforcement Calculator), was created by Marvin Minsky and Dean Edmonds as part of their undergraduate work at Princeton University in 1950. The early ANNs were used to calculate mathematical functions; therefore, they should not be regarded as AI but rather as *pre-AI*. The popularity of ANNs rose in the mid-1980s, when computers became sufficiently fast to cope with ANNs of a useful size. Today, ANNs are the most often mentioned forms of AI; they occupy much of the AI landscape, including machine learning.

Any ANN consists of three sets of artificial neurons: There is an input layer, which receives a signal (stimulus); then, there is a hidden layer, which performs a translation or *black-box* operation; and finally, the output layer, which produces a response. The artificial neurons are connected to each other across the layers, resembling synapses in a brain. The response is compared with the expectations, the initial weights are amended, the process is repeated iteratively, and ANN will relatively quickly adjust and produce the desired response. In other words, ANNs learn from a large number of learning examples how to reproduce their statistical frequency. The often-mentioned *deep ANN* and *deep learning* simply mean that there is more than one layer of artificial neurons in the hidden layer.

When it comes to facts and beliefs, it is useful to consider how similar ANN is to the brain. The size of the human brain is estimated at around 80 to 100 billion neurons, each with around 7,000 connections on average, resulting in about 700 to 1,000 trillion (10^{15}) synapses in total. The largest ANN today consists of some 16 million artificial neurons, which roughly corresponds to the size of

a frog's brain. Thus, in terms of synapses, we may be about 8 to 10 orders of magnitude short of the size of the human brain. At the same time, an ANN of 16 million neurons is already so large that the architect cannot grasp it anymore, and it takes a long time to train even using supercomputers. So, if it is even possible to approach the size of the human brain, this will not happen any time soon.

Structurally, ANNs are layered, and the connections usually only go forward (in some networks, there are also within-layer connections). The human brain is a complex network of neurons, so the idea of layered structure may not apply, and there may be circular connections. Functionally, an ANN reflects what was known about biological neurons around the mid-20th century: At any time, neurons are either *firing* or not. Today, it seems that at least a small subset of neurons (perhaps a few million?) display more complex behavior; that is, the strength of the firing impulse seems to matter. Individual neurons also display very different behaviors in this respect, and the strength of firing impulse can vary two orders of magnitude. All this means that structurally and functionally, ANN is rather limited in comparison with the human brain.

However, if ANN architects managed to construct something that resembles an artificial brain in terms of size, structure, and function, there is another belief that must be confronted: that the artificial brain would produce an artificial mind. What is known so far is that brain and mind are somehow connected, and particular thinking processes can be associated with activity in particular brain areas. We still lack an understanding of how the brain and the mind are linked.

Finally, according to recent research besides the brain, other organs, for example, the endocrine system, may be part of our cognitive system. It is not impossible that the mind is fully *embodied*, meaning that the whole body is part of it. So, an artificial brain may or may not produce an artificial mind.

Can AI Think?

Since the very beginning of AI, the big question has been: How do we know if AI should be considered (artificially) intelligent? The first criterion, proposed by Alan Turing in 1950, is still the most popular today. The essence of the Turing

test is that if we communicate with an entity and cannot figure out whether it is a person or a machine, and in fact it is a machine, it means that the machine *thinks*, and it should be considered intelligent. At first sight, this argument may sound convincing; if the machine is not really thinking, we should recognize this. Not everything is, however, as it seems. The first program that passed the Turing test was Joseph Weizenbaum's ELIZA, created in 1966, followed by many other programs, up to today's chatbots. However, these programs passed the test with people who did not know that they were testing. The first experiment that was actually set up as a test was Eugene Goostman, the simulated 13-year-old Ukrainian boy. The legitimacy of this test can be questioned, but, as noted by Stuart Russell and Peter Norvig, it fooled 33% of the untrained amateur judges. So, the judges might not be right and 33% is quite low. In addition, the setup certainly worked in favor of the outcome: having someone who is 13, from a country about which the testers do not know much, speaking English as a foreign language. As Russell and Norvig speculated, perhaps the Turing test is really a test of human gullibility.

It is possible, however, that an AI will at some point legitimately pass the Turing test—but there are further problems. Turing modeled his test after the *imitation game*. In this game, Person *A* pretends to be Person *B*. If *A* has learned a lot about *B*, the testers may believe that *A* is *B*. However, this does not mean that *A* actually became *B*. The programs that passed the Turing test were designed with the purpose to pass the test, not with the purpose to think.

An excellent explanation of the Turing test is the *Chinese room argument*, proposed by the philosopher John Searle. The essence of the argument is the following: A person who does not speak Chinese is in a room full of rule books, receiving messages in the form of Chinese symbols and looking up responses to those messages in the rule books. If the rule books are good, those reading the responses outside the room may believe that the person responding speaks Chinese. Similarly, passing the Turing test does not prove that the computer thinks, only that the program is good.

Of course, none of these instances prove that machines cannot think; they only point out the

lack of conclusive proof. So, we are left to our respective beliefs.

AI Paradigms

The distinction between *strong AI* and *weak AI*, as the two paradigms of AI research, was introduced by Searle, the author of the Chinese Room Argument. The strong AI paradigm postulates the idea of the thinking machine—of AI with a mind of its own, at least—as a desirable and achievable outcome. Most followers of strong AI do not believe that AI can currently actually think, but they do believe that it is only a matter of time until it will. Typically, this is fueled by the beliefs described in the previous and following sections of this entry. Marvin Minsky, a great proponent of strong AI, suggested that any endeavors in the field of AI, other than trying to create AGI, are meaningless.

In contrast, those who follow the weak AI paradigm see AI as a technology that can help produce useful and powerful tools. Many of them do not believe in the possibility of AGI, and none of them work on the AGI project. They argue that we cannot produce an artificial mind, as it would require the researchers to obtain a complete understanding of the mind, which they believe to be impossible. There is a very important consequence of this belief on what and how the followers of weak AI try to achieve in their work. They do not try to replicate the human thinking process; instead, they try to find a sensible way of achieving the same or similar performance. A popular metaphor used to describe this is the relationship between the horse and the car. When the original creators dreamed up the first automobile, they did not attempt to replicate the muscles, joints, and metabolism of a horse; they used an internal combustion engine instead, and put it on wheels. The car can be an excellent replacement for some aspects of the horse; for instance, it can take passengers from one place to another (more passengers than a horse, more conveniently and usually faster). In other areas, however, such as playing polo or enjoying horseback riding, the car cannot deliver. Similarly, what weak AI researchers produce only works in a narrow area and in very different ways from how humans would deal with the task.

Curiously, although their beliefs are fundamentally different and they focus on different types of work in the area of AI, the followers of the two paradigms do agree about one thing: that what is missing to achieve a thinking machine is common sense. As all human beings have common sense, it is sometimes considered to be something simple—but it is not. According to Minsky (1988, p. 22), common sense consists of “hard-earned practical ideas—of multitudes of life-learned rules and exceptions, dispositions and tendencies, balances and checks.” It only appears simple because we do not recall acquiring it.

AI and the Human Mind

There are several areas that people think of as particularly human, such as knowledge, learning, and creativity. It is useful to look at the differences between the human mind and AI along these dimensions that can be conclusively demonstrated.

The difference that is the easiest to identify along the knowledge dimension is that systems that rely on knowledge acquisition are necessarily limited to explicit knowledge. According to the Hungarian–British polymath Michael Polányi, all human knowledge is either tacit or rooted in that which is tacit, as all explicit knowledge relies on being tacitly understood and applied. The problem of common sense showcased in the previous section can be explained similarly: Common sense is predominantly tacit, and all human knowledge incorporates common sense. *Intuition*, which has been deemed valuable in relation to peak human achievements (such as scientific discovery, artistic creativity, and managerial decisions), also belongs to the tacit realm. Humans also know *harmony and beauty*, and this beauty usually drives creative achievements, deep thoughts, and simply provides joy. For instance, a human can admire the beauty of a rainbow despite knowing that it is the result of the prism effect. People also use *analogical thinking*, which refers to mental models analogical to reality. An extraordinary example of this is the Serbian–American inventor Nikola Tesla (1856–1943) designing his machines entirely in his mind, without using a blueprint. Finally, *seeing the essence* is an achievement unique to the high levels of human expertise. It consists of two parts: the *big picture* and the detail. Those who achieved

a high level of expertise are known to see the *big picture*. However, they can also see any of the details, as well as the relationship between the details as well as the relationship of the details to the big picture, and they can rapidly switch from one to the other.

Besides the many aspects of knowledge that do not seem to be easy to replicate or emulate with AI, knowledge also relates to other aspects of our being. Humans also have *feelings*, which are manifestations of biological drives such as hunger, fear, longing for the company of other people, and so on. While humans can temporarily override their feelings, using their knowledge—for example, we do not need to eat right away when we start feeling hungry—*emotions*, in turn, can override knowledge. Our important decisions, such as whom to marry, where to live, or what organization to work for, have significant emotional components. Minsky goes so far as to suggest that knowledge is impossible without emotions. Humans also have *values* embedded in their knowledge. For instance, sometimes they do not do what matches their well understood preferences but what they think is the right thing to do.

The situation with learning is similar to the situation with knowledge. Reinforcement learning, which is how ANN learns, is only a tiny part of human learning. There was a time when psychologists thought that all human learning is a variant of reinforcement learning, but psychology has come a long way over the past 70 years. The significance of talent has been discovered, the significance of which is that people learn faster in areas in which they are talented, and learning in these areas feels mostly like playing. AI learns equally in all areas. People get inspired and interested in various things, and inspiration and interest can make them invest extra efforts in learning what they like. Furthermore, those who achieved the highest level of expertise all went through some form of master–apprentice relationship. All people have some such experience; for instance, this is how we learn our native language. This immensely complex form of learning builds on a deep personal connection between master and apprentice, and our understanding of how it works is very limited. What we do know, however, is that the master–apprentice relationship seems to be the only way of transferring tacit knowledge.

Finally, there is a question if AI can be creative or not. It certainly outperformed top human experts in areas where creativity is considered important. Examples are Deep Blue winning against chess grandmaster Garry Kasparov in 1997, and AlphaGo defeating Lee Sedol in 2016 (as well as all the other Go grandmasters shortly after that). Human creativity is defined as the production of a new and useful idea—AI has definitely produced new and useful things, but it can be argued that it has never produced an idea. However, AI can certainly support human creativity, producing patterns from large amounts of data as well as helping us transcend the boundaries of our knowledge traditions.

Concluding Remarks: How to Think and Talk About AI

This entry has described what AI can do and what its limitations are; the entry has also delineated the facts and beliefs regarding current performance and future promises. AI comprises an exceptionally powerful set of technologies and may well be the most expensive human enterprise ever. If we use it well, it can greatly benefit the whole of humankind.

What can be done to get things right about AI? Perhaps it would be a good start to stop describing AI in human terms: *Human–AI collaboration, thinking, learning, and making decisions* are all terms that attribute intentionality to AI—something that it most definitely does not currently have, and possibly never will. Even when we talk about authentic AI, we usually think of a better fake human. Authentic AI, however, is not human-like; it is AI-like. For a human future in which AI plays a great role to the benefit of humankind, we need authentic humans as well as authentic AI.

ASSUMPTION

Our contemporary word *assumption* is derived from the Latin word referring to the act of being taken up or received. In that context, the Catholic Church used the word to articulate the Assumption

of the Virgin Mary—that is, the official dogma that she was taken up bodily into Heaven. That use remains today, but beginning in the 13th century the word slowly took on the broader meaning of any idea, premise, or axiom that is *taken up* or taken for granted. With this latter meaning in mind, in what follows, a definition of assumption is offered and explained point by point, giving examples along the way as the term relates to both theory and human life. From there, a few additional examples are provided of the importance and place of assumptions in theory and theory building, spanning not only the physical sciences and mathematics but also the social sciences. The entry concludes with a brief summation of the place and importance of assumptions in theories.

What Is an Assumption?

Assumptions are beliefs of a particular kind—namely, assumptions are propositions that persons (and in the aggregate, human groups or even entire societies) regard to be true, whether consciously or tacitly, and which form the basis of—rather than being conclusively inferred from—processes of reasoning and lived experience. This definition requires some unpacking. First, assumptions are propositional, but oftentimes this is the case merely in the sense that, in principle, they could logically be articulated as propositional statements (unlike, for instance, some kinds of emotional states). In other words, assumptions are propositional not in the sense that they are necessarily or even usually propounded and spelled out in explicit propositional form. But assumptions are propositional in the sense that they make claims regarding what is true about reality and those understandings—even when left unstated—can be either true or false.

Secondly, assumptions are not free-floating ideas but are believed by persons and often also by groups, subcultures, or societies. It is not hard to grasp that persons hold fast to assumptions. But when persons gather, interact, or even share some common social identity from a distance, their association is likely to give rise to (or be premised upon) taken-for-granted ideas, values, and axioms. The first-generation college student group at the state university likely holds certain assumptions—about class mobility, equality, and

the purpose of higher education—which take intentional work to see and to understand. It is also possible for the vast majority of a society to hold to an assumption that is rejected by a subcultural subset within it. For example, the popular assumption in Western modernity that what is morally right and good is ultimately up to each individual to decide is rejected by many conservative religious thinkers and some philosophers.

Third, assumptions can function anywhere along a spectrum from conscious to routinized to subconscious, being explicit or left implicit. In some cases, assumptions are stated up front and explicitly recognized as providing the grounds for some subsequent argument, observation, or experience. This is the case, for instance, in many philosophical arguments (especially those in analytic philosophy using formal logic) as well as in the mathematical proofs, one undertakes in algebra or geometry classrooms. In this sense, assumptions are rightly understood as taken-for-granted premises, the logical givens that set the stage for what comes next in the course of making a case or building an argument. In other cases, assumptions are known but nevertheless left unexpressed. For example, an evangelical Christian might try to organize her life and beliefs around the idea that the Bible alone is God's authoritative Word to humans. Such a baseline assumption would presumably have a powerful guiding effect on her life and beliefs even if most days it does not come up in conversation, but if asked she would be readily able to express it.

At still other times, assumptions operate on a level that is wholly unrecognized and implicit. Persons can hold assumptions without even knowing that they hold them, and persons can be powerfully influenced by those assumptions without recognizing it. Assumptions—as a particular kind of belief—need not be reflected upon, consciously adopted, or able to be stated in order to be genuinely believed. This does not mean, though, that such assumptions must always stay at the prediscursive, implicit level of consciousness. It is often possible for another person to point out and articulate a previously unrecognized assumption, at which time that assumption might move from unrecognized to recognized, from implicit to explicit. It is even possible for a person to identify her own previously unrecognized assumptions and change them if necessary.

Sometimes this is difficult, requiring study, dialogue, and critical reflection. Other times, this does not take much. Persons often do not realize they had been holding some assumption until it turns out to be false: You return home from a weeklong vacation only to discover that you had wrongly assumed that your spouse had locked the front door. You arrive at your favorite coffee shop to meet a friend, not having considered that she meant the one on the other side of town.

Fourth, assumptions are not (and cannot be) conclusively inferred or verified from reason or experience. Against the tradition of rationalism, taking assumptions seriously in life and in academic theorizing requires the recognition that reason, rationality, and logic are never the only factors at play. Likewise, against the tradition of empiricism, seriously accounting for the role of assumptions in life and theorizing necessitates moving beyond a strict focus only on what can be observed from experience and the five senses. Instead, assumptions are precommitments and premises that come before either reason or empirical experience. In the language of epistemology (the philosophy of knowledge), an assumption can be *justified* (i.e., a person is not always being cognitively reckless or intellectually sloppy for believing it) without being *justifiable* (i.e., without being able to be verified through argumentation and evidence). This does not mean that assumptions cannot be supported or made compelling through reasoning and experience. If an assumption meshes well with one's lived experience and helps to make the world intelligible, then there is good reason to hold to it. It is justified. But it cannot be conclusively established or deduced with indubitable certainty through the use of reason or observation. It is not justifiable.

Fifthly, basic assumptions form the grounds for processes of reasoning—ranging from particular instances of philosophical argumentation and mathematical proofs to more general approaches to (or convictions about) what knowledge is and how humans can go about acquiring it. This is most easily seen in simple logical syllogisms, in which a major premise and a minor premise are used to deduce a conclusion. But even in more complex belief structures and systems of reasoning, assumptions can serve the role of basic (and powerfully life-guiding) beliefs. That is, certain

kinds of beliefs—such as that a divine being exists, that one's memories really do refer to actual past happenings, or that natural science is the only rational way to reach conclusions—can *sit at the bottom*, so to speak, of one's system of beliefs or worldview. Such basic beliefs are not inferred from, or held on the grounds of, other beliefs that the knower regard to be true. And different persons (and human groups) can and do hold to differing beliefs in this basic way. This pluralistic nature of basic starting points has led many philosophers of knowledge away from foundationalism (i.e., the theory that all humans share some common, incorrigible foundation for knowledge) to what is known as *post-foundationalism*. This is also why it might seem like a life-altering paradigm shift when one's basic beliefs and assumptions, for some reason, are revised.

Sixth, assumptions and premises are crucial not only for theory and theorizing but also for human experience and life in the world more broadly. The propositional content of assumptions can range from the mundane (“Oh, I assumed you were going to buy the milk”) to big questions in the realms of epistemology, metaphysics, and ethics. And to the extent that abstract ethical, epistemological, and metaphysical issues and ways of thinking influence the ways persons live, even seemingly distant assumptions turn out to have serious consequences on actual experience. On this point, some philosophers and social scientists emphasize the principle of *practical adequacy*, which suggests that when the components of human knowledge systems (including one's assumptions) *rub up against* practical activity in the world in a way that makes the world and life unintelligible or unlivable, there is good reason to suspect that some crucial part of that knowledge system is problematic (i.e., false) and thus may need to be reconsidered and revised.

Examples of Assumptions

Assumptions play a central role in theories and theory building in several ways. In the social sciences, for example, assumptions about the nature (or lack thereof) of human beings are multiple and lead theorists in different directions. Some theorists hold a social collectivist view that claims human beings are ultimately a product of the

cultural environments in which they are embedded, such that they are primarily concerned with living out their society's norms and values. Other theorists assume a fundamentally economic view of humans as self-interested rational actors, seeing humans as driven by cost-benefit calculations in order to maximize their utility. Other theorists, influenced by postmodernism and phenomenology, view human identity and selfhood as fragmented, transient, and variably constructed across different situations—lacking any essential nature. Still other theorists adopt a sociobiological and evolutionary view of humanity, in which all of human social life can be explained by reference to *survival of the fittest* and the functioning of genetic material. And some theorists hold to an Aristotelian view of human beings as persons with an essential shared human nature and a moral direction toward which to strive for their objective flourishing. Which of these models of human nature is taken for granted clearly would have a great impact on a social scientist's explanations and theories.

Another example can be drawn from the history of geometry. In the third century B.C.E., the Greek mathematician Euclid systematized geometry based on five axioms, from which more complex theorems could be deduced. These five axioms involved the relationships between lines, points, and angles (e.g., between any two points there is only one line segment with those points as end points). For more than 2,000 years, this axiomatic system was the only version of geometry. But over the centuries, several thinkers questioned whether Euclid's fifth axiom (namely, that for any line and a given point off that line, there is only one line that runs through that point and parallel to the first line) was self-evidently true. Several attempts to prove the fifth axiom based on the first four ended in failure. Beginning in the early 1800s, mathematicians started to imagine what alternative geometric systems would look like if Euclid's fifth axiom—known as the *parallel postulate*—could be false. The result was a variety of non-Euclidean geometries, in which the spatial grid on which geometry is done is not a boxy, straight *Euclidean space*, but instead is intrinsically curved in various ways. This questioning of Euclid's fifth assumption and the recognition that spatial grids can be curved helped to shift the way physicists think about space and

set the stage for Albert Einstein's theory of general relativity and gravitational force.

Even the scientific method operates on the basis of a handful of assumptions that cannot be verified using the scientific method. For example, science proceeds on the presupposition that there exists a real world about which scientists are trying to gain knowledge and that this world has a structure and nature independent of our theories about it. Scientific inquiry and discovery also makes sense only if scientists believe that aspects of the physical world (such as the laws of physics or the basic features of biology) will work very similarly tomorrow as they have worked in the recent past. Likewise, the scientific method assumes that human cognitive and sensory faculties are fairly reliable tools for gathering and interpreting data. Even more basically, science proceeds under the supposition that some beliefs and theories are closer to the truth than others; all is not relative. Science even makes moral assumptions—such as that theories should be tested fairly, that findings should be reported honestly, and that it is better to believe what is true than what is false. As assumptions, such beliefs are not necessarily unjustified or wrong, but they are nevertheless not definitively verifiable by logical proofs, arguments, or empirical observations.

Conclusion

It is not necessary—and probably not possible—for every unverified assumption to be articulated in theory and research. But clearly, assumptions are both important and unavoidable. While some scholars may feel the urge to hide, ignore, or deny the premises and assumptions that underpin their work, it is best as much as possible to be aware of the assumptions that one is making. And beyond just reflecting upon and recognizing one's assumptions, it is important as well to be willing to question and possibly to change them when the data and evidence call for it. Even the most fair-minded scholarship does not operate with a God's-eye view or with every idea or belief established with absolute certainty. But with sustained and critical attention to the assumptions undergirding scholarship, development of theory can proceed on a steady footing.

AUTHORITY

The concept of authority is fundamentally related to the concepts of hierarchy, power, and obedience. In modern research on authority, the concept has been articulated and operationalized in a number of different ways. Scientific discourse is discussed in terms of its influence and paradigmatic power, intrinsically linked to its authoritativeness. Political scientists refer to systems of authority and how they relate the role of the state. Psychologists refer to the relationship between authority and obedient behavior.

The word *authority* is etymologically rooted in Latin and is connected with the words *auctoritas* and *auctor*, which reference “one who originates or promotes ideas.” In Old French, the term *autorité* is itself related to the Old English term for *author*, again referencing “one who originates.” These roots are reflected in the general concept of authority as “one who originates or issues command or orders,” ostensibly to be obeyed by those subservient to the person, their social role, and/or the orders. Conceptually speaking, these dynamics naturally invokes reference to the constructs of hierarchy and the power differentials that underlie

and support a hierarchical social system. Philippe Aghion and Jean Tirole note the distinction between *formal* and *real* authority in organizations, the former being ascribed to an office who holds power by virtue of the position (e.g., a chief executive officer, or CEO, who may not actually make real decisions impacting organizational goals) and the latter having the ability to make decisions on the basis of authority granted by the superior.

This entry considers the varying conceptualization of authority, and how they have been reified in scientific, political, religious, and psychological narratives. This list is by no means exhaustive but is meant to synopsise some of the most prominent discourses that have been developed around explicating authority and how it structures human behavior.

Scientific Authority

Scientific discourse is powerful and influential to the extent that it is considered authoritative. Thomas Kuhn described the manner in which scientific theories come to dominate others and eventually become widely accepted as lenses through which problems are both conceptualized and solved. In his influential book *The Structure of Scientific Revolutions*, published in 1970, Kuhn describes the social process whereby scientific theories become authoritative, a point to which he ascribes the term *paradigm*. Scientific paradigms do change over time, largely due to the presentation of anomalies that cannot adequately be addressed or resolved within the context of the dominant paradigm of the time. When this happens—and Kuhn suggests that it is ultimately inevitable—a paradigm shift occurs whereby novel, unanticipated solutions to the anomalies arise, and achieve acceptance in the wider scientific community. Over time, the new paradigm comes to be accepted as authoritative among the scientific community and society in general.

Political Authority

Political authority is a concept that is intrinsically linked with the concepts of power and legitimacy. Power, in its most abstract conceptualization, typically entails the ability to influence others behavior beyond what they would ordinarily do, and

legitimacy is most often conceptualized as a form of government which citizens believe is appropriate for that society. C. W. Cassinelli noted that legitimacy and political authority almost always involve an element of coercion, but can never involve force or the explicit threat of it; to do so is to undermine the extent to which one is truly considered a political authority.

Max Weber (1864–1920) developed a typology of political authority in his treatise “The Three Types of Legitimate Rule”: traditional, legal-rational, and charismatic. Weber’s three types of authority represent ideals, and thus do not necessarily correspond precisely with any given socio-political entity. In addition, authority can evolve from the lowest form into one of the other, more advanced, forms. *Charismatic authority* is described as a social arrangement wherein leaders derive their power on the basis of their possession of some type of extraordinary attribute or supernatural power. Those subject to this type of rule must inherently believe in the power granted the leader. A contemporary example of a state predicated upon charismatic authority is North Korea under the totalitarian rule of the Kim family. The Kim family began their reign with Kim Il Sung, a leader whose persona was so elaborated by means of state-controlled propaganda, he continued to serve for years after his death as the world’s only posthumous president.

Traditional authority arises from longstanding custom and is the basis of authority for monarchies. The death of a charismatic leader can result in the formation of a system whose authority derives from tradition. This type of authority is oriented toward maintenance of the status quo ante and its inherent inequalities. Beyond the domain of nation-states and their form of political organization, an example of this type of authority can be found in patriarchal societies, wherein the inherent inequality between men and women has been established not on the basis of charisma (or rational principles) but solely on the basis of longstanding custom.

The *legal-rational system of authority* is organized such that citizens are subservient to a legal structure that has been rationally constituted, rather than to a particular person, as is the case within a system predicated upon a charismatic or traditional form of authority. That legal structure

can take the form of a constitution, a static form of bureaucratic organization, or rationally derived codified principles that establish the legality, responsibilities, and conditions of rule. Typically, under this form of authority, citizens are deferential to the office wherein power is vested, and not to the particular officeholder who happens to fulfill that social role. As an example, 21st-century Japanese, British, or Canadian political authority would be characterized as legal-rational in organization.

Religious Authority

Mark Chaves defines religious authority as “a social structure that seeks to enforce its order through the legitimate control of some supernatural component” (1994, p. 750); where authority withholds access to something vis-à-vis the legitimacy of the supernatural, that authority is religious. The goods that religious authority might control vary between religious traditions (e.g. eternal life, an end to suffering, or prosperity). Authoritarianism has been linked with religiosity and is a social attitude that refers to individuals who hold conservative principles and are generally accepting of established authorities. Authoritarians and deeply religious people tend to share common values, preferring the status quo over change, and employing a noninterpersonal morality that refers to external sources of authority (e.g., group norms).

Psychological Authority

The psychological literature has considered the nature of authority as it manifests itself in interpersonal relationships (such as between parent and child) and how authority is related to obedient behavior. The scope of discourse surrounding parental authority generally concerns parents’ ability to utilize one of two types of control: psychological control and behavioral control. Psychological control involves any attempt by parents to encroach upon a child’s psychological and emotional development. It typically takes the form of manipulative tactics in order to achieve its goal. Behavioral control refers to parental attempts at managing a child’s behavior, such as correcting a child’s inappropriate behavior with punishment.

Psychological control is most potent in young people before and during adolescence and is sometimes thought to be a parenting style as opposed to a parenting practice. This type of control does not necessarily involve parental pressure to feel and think in ways dictated by parents; it can merely embody parental pressure aimed at making the child behave in accordance with parental expectations. Tactics like guilt induction help parents maintain legitimate parental authority over issues of concern, like child friendship affiliations. Parental control can sometimes intrude upon a child's psychological development. Where it does, empirical evidence suggests that the negative consequences of this control can be predictive of later mental health issues and behavioral disorders. Where it concerns behavioral control, research on parental authority suggests that it is not counterproductive unless it impairs the bond between parent and child; harsh or erratic levels of punishment are predictive of later involvement in activities such as delinquent behavior.

Parents are encouraged to balance appropriate control over their children's behavior with developmentally appropriate attempts to give them autonomy as they grow older. Younger children are more accepting of parental authority and its legitimacy; however, some have found that as children aged, their views on parental authority become less positive. Where it concerns the scope of parental authority, there appear to be clear boundaries with regard to what constitutes legitimate parental authority and what should remain under the jurisdiction of children.

Stanley Milgram and *Obedience to Authority*

One of the most controversial and thought-provoking research projects aimed at understanding the nature of authority was psychologist Stanley Milgram's work at Yale University concerning obedience to authority figures. His research, first described in the *Journal of Abnormal and Social Psychology*, was published contemporaneously with Hannah Arendt's coverage in 1961 of the Adolf Eichmann trial for *The New Yorker* magazine, the hugely consequential trial of a former German bureaucrat instrumental in supervising, organizing, and facilitating the systematic extermination of

European Jews, or *Jewish Affairs*, as it was euphemistically put in German bureaucratese. Fifteen years after the close of the war, Eichmann had been discovered living in Argentina by the Simon Wiesenthal organization; he was subsequently abducted by Mossad, the Israeli intelligence agency and smuggled back to Israel on a commercial flight to stand trial as personally accountable for his role in the murder of 6 million Jews.

Milgram was explicit about his interest in exploring the social dynamics that had facilitated the implementation of the Final Solution to the Jewish Question, the event now formally referred to as *the Holocaust*, and intended to compare levels of compliance in Germany with those in the United States. Aside from inspiring an onslaught of critique from research ethicists, his 1974 book *Obedience to Authority: An Experimental View* exposed a social dynamic whereby free will can be truncated, overridden, in the name of obedience to those who are perceived to constitute legitimate authorities.

The experimental design saw to it that experimental subjects administered an incrementally more intense series of electric punishment shocks to an ostensible *subject* (in reality a confederate of the experimenter) under the guise of its being a test of negative punishment's effect on learning capability. The coercive prompting of a confederate *researcher*, playing the role of a legitimate authority figure, insisted at appropriate times that subjects continue with the experiment despite any protests they might have to delivering increasingly strong electrical shocks to the victim, the bogus *subject*. Milgram performed many permutations of the relationship between the various actors involved in the experiment—altering in varying degrees the proximity of the victim, confederate researcher, and the experimental subject in order to test whether social distancing had an impact on a subject's obedience to orders, which was generally found to be the case.

Replications of the shock experiments were canceled in Hamburg, Germany, when Milgram found levels of compliance in the United States (the control group) high enough to rule out meaningful comparison with what he originally conjectured would be a more obedient German population. To the lament of the predictions of the psychiatrists Milgram had surveyed beforehand, roughly two-thirds (66%) of the subjects in Milgram's experiments were fully compliant in

harming (and ostensibly killing) the confederate victim. The dynamic that Milgram exposed was one whereby personally injurious behavior need not be related to any moral, psychological, or biological factors impacting the experimental subject. Milgram's overall findings are compatible with the sincerity of the defense cliché espoused by those tried for offenses against humanity at Nuremberg and elsewhere: that they were merely *following the orders* of their superiors, presumably because they did not have the grounds to question the legitimacy of that authority, or the commands issued forth.

AXIOM SCHEMA

An *axiom schema* (plural: *schemata* or *schemas*, from the Greek *skhēma*, meaning *form* or *figure*) is a *template* for an axiom, accompanied by a *rule* that tells us how to instantiate the template with

specific expressions in some (formal) language to produce an axiom. Thus, in developing an axiomatic theory in logic, mathematics, or science, one uses axiom schemas to specify a collection of axioms representing the basic or fundamental assumptions of the theory, from which one derives all other implications of the theory (i.e., its *theorems*). However, there will typically be *infinitely* many such axioms and so some method is needed to specify all of them at once by finite means. It is primarily because of this that we require the templates for axioms known as *axiom schemas*.

It is worth noting that *axiom schemas* are just one instance of the slightly broader notion of a schema, used in both logic and mathematics. The broader notion includes templates both for the axioms of a theory and so-called *rules of inference*, that is, rules for deducing consequences from the theory's axioms or from previously established theorems or previously made assumptions. Because there will also be an infinite number of ways of applying a given rule of inference, a schema for representing this rule by finite means is also needed. This entry discusses examples of axiom schemas in both logic and mathematics.

Axiom Schemas in Logic

Axiomatic systems in logic, often called *formal systems* or *logical calculi*, allow us to determine which statements in a formal language are logical validities, either because they are axioms themselves or because they are logical consequences of axioms. For example, in a *Hilbert system* for propositional logic, an approach that emphasizes axioms and minimizes the role of deductive inference rules, the following expressions are examples of axiom schemas:

$$P1: (\phi \rightarrow \phi)$$

$$P2: (\phi \rightarrow (\psi \rightarrow \phi))$$

$$P3: ((\phi \rightarrow (\psi \rightarrow \chi)) \rightarrow ((\phi \rightarrow \psi) \rightarrow (\phi \rightarrow \chi)))$$

$$P4: ((\sim(\phi) \rightarrow \sim(\psi)) \rightarrow (\psi \rightarrow \phi))$$

In each of these four axiom schemas, we have expressions representing logical connectives; here

the arrow, “ ρ ,” represents material implication and the tilde “ $\sim$ ” represents negation. Other systems might also involve symbols for disjunction (“ $\vee$ ”), conjunction (“ $\wedge$ ”), and the biconditional (“ $\Leftrightarrow$ ”). Technically, the left and right parentheses are also part of this logical vocabulary, necessary for indicating and disambiguating the scope of the logical constants. We also have the expressions “ ϕ ,” “ ψ ,” and “ χ ” representing arbitrary well-formed formulae in the formal language in which the system is expressed. These latter expressions are sometimes called *metalinguistic variables* as they are not themselves expressions in the formal language of the system but are expressions from the *metalanguage*, the language we use to talk about and study the formal language and properties of the system. Thus, in contrast to the metalanguage, the language of the system itself is called the *object language*, and, in the context of propositional logic, the metalinguistic variables range over the class of well-formed formulae (or *wffs*) in the object language. Most commonly either Greek letters or uppercase Latin letters ($A, B, C, \dots$) are used to denote metalinguistic variables.

Each of P1 through P4 is thus a template in the sense of being a string of symbols that outlines and represents the shape or form that an axiom in the Hilbert system of propositional logic can take. However, these axiom schemas also implicitly involve a *rule* indicating how they are to be instantiated or *filled in* for the sake of producing a genuine axiom expressed in the language of the system itself. That rule is implicit in the range of values that the metalinguistic variables, “ ϕ ,” “ ψ ,” and “ χ ” can take, which is here stipulated to be the class of well-formed formulae of the formal language of propositional logic. To show what these instances might look like we can first briefly sketch a formal language for the propositional logic embodied in this Hilbert System:

Let L_{PROP} be the language of propositional logic, defined as the following set of wffs:

- i. $P_i \in L_{PROP}$, for every $i \in \mathbb{N}$
- ii. If $\phi \in L_{PROP}$ then $\sim(\phi) \in L_{PROP}$
- iii. If $\phi, \psi \in L_{PROP}$ then $(\phi \rightarrow \psi) \in L_{PROP}$

- iv. Only expressions formed by applications of (i)–(iii) are wffs of L_{PROP} .

Thus, applying these formation rules, the following strings of symbols are all examples of well-formed formulae in L_{PROP} :

- a. $P_1 \rightarrow (P_4 \rightarrow P_{23})$
- b. $\sim (P_2 \rightarrow P_{217}) \rightarrow (P_{1300} \rightarrow (P_{14723} \rightarrow \sim (P_0)))$
- c. $P_5 \rightarrow ((P_7 \rightarrow (\sim P_9 \rightarrow P_{11})))$

Procedurally, having first specified a formal language for propositional logic so that we now know what counts as a wff, the axiom schemas P1 through P4 are then introduced to specify which specific wffs in the language count as axioms of the deductive system. The following are therefore axioms of the system as they are instances of the axiom schemas P1 through P4, respectively:

$$\begin{aligned} &(P_7 \rightarrow P_7) \\ &(P_7 \rightarrow (P_{10} \rightarrow P_7)) \\ &(P_2 \rightarrow (P_{111} \rightarrow P_{6455})) \rightarrow \\ &((P_2 \rightarrow P_{111}) \rightarrow (P_2 \rightarrow P_{6455})) \\ &((\sim P_5 \rightarrow \sim P_{108044}) \rightarrow (P_{108044} \rightarrow P_5)) \end{aligned}$$

The following more complicated formulae are also axioms and instances of P1 through P4, respectively:

$$\begin{aligned} &(P_7 \rightarrow (P_{42} \rightarrow (P_{500} \rightarrow P_{99}))) \rightarrow \\ &P_7 \rightarrow (P_{42} \rightarrow (P_{500} \rightarrow P_{99})) \\ &(\sim (P_{80} \rightarrow P_7) \rightarrow ((P_{10} \rightarrow P_{778}) \rightarrow \\ &\sim (P_{80} \rightarrow P_7))) \\ &(P_2 \rightarrow (\sim (P_{111}) \rightarrow \sim (P_6 \rightarrow P_{89}))) \rightarrow \\ &((P_2 \rightarrow \sim (P_{111})) \rightarrow (P_2 \rightarrow \sim (P_6 \rightarrow P_{89}))) \\ &((\sim (P_7 \rightarrow (P_{10} \rightarrow P_7)) \rightarrow \sim (P_{10} \rightarrow P_{778})) \rightarrow \\ &((P_{10} \rightarrow P_{778}) \rightarrow (P_7 \rightarrow (P_{10} \rightarrow P_7)))) \end{aligned}$$

The axioms can thus become almost arbitrarily complex. In a Hilbert system for propositional logic, the axiom schemas are typically also supplemented with a schema for a rule of inference indicating how one formula may be permissibly transformed into another within the system. A common example of a rule used in this context is *modus ponens*:

$$\frac{(\phi \rightarrow \psi) \quad \phi}{\psi}$$

This rule tells us that from any pair of formulae that have the schematic forms represented by “ $(\phi \rightarrow \psi)$ ” and “ ϕ ” we can infer a formula with the form represented by “ ψ .” Again, there will be infinitely many pairs of formulae that have this form, and so the modus ponens schema allows us to generalize over all of them by finite means.

In more powerful logical languages and systems, such as the first-order predicate calculus and axiomatic systems of first-order logic, axiom schemas are again used to specify an infinite collection of axioms by finite means. However, unlike with those of propositional logic, the templates and rules for axiom schemas in first-order logic also deal with expressions of types other than just the wffs in the language, in line with the greater expressive power of the predicate calculus. The following axiom schemas for the universal quantifier “ $\forall$ ” in first-order logic illustrate this difference:

$$\text{PC1: } (\forall \alpha (\phi) \rightarrow \phi(\beta / \alpha))$$

$$\text{PC2: } (\forall \alpha (\phi \rightarrow \psi) \rightarrow (\forall \alpha (\phi) \rightarrow \forall \alpha (\psi)))$$

$$\text{PC3: } (\phi \rightarrow \forall \alpha (\phi)) \text{ when “}\alpha\text{” is not free in } \phi$$

In PC1, the expression “ $\phi(\beta/\alpha)$ ” indicates a metalinguistic variable for a wff that is exactly the same as that instantiating the metalinguistic variable “ ϕ ” *except* that it may differ (at most) in having the term that instantiates the metalinguistic variable “ β ” substituted for all occurrences of the bound term instantiating the metalinguistic variable “ α .” PC2 is more straightforward, indicating that the universal quantifier binding a term distributes over the material conditional. Finally, PC3

tells us that all instances of the conditional “ $(\phi \rightarrow \forall \alpha (\phi))$ ” are axioms whenever the bound term instantiating the metalinguistic variable “ α ” does not occur unbound (*free*) in the wff instantiating the metalinguistic variable “ ϕ .” As such, we can see that axiom schemas for axiomatic systems of first-order logic require variables for expressions other than wffs, that is, they require variables for *terms* (where the terms include variables, constants, and function applications in the language of the predicate calculus). Relative to a first-order language with variable terms “ $x_0, x_1, x_3 \dots$,” constant terms “ $c_0, c_2, c_3 \dots$,” (unary) function terms “ $f_0, f_1, f_3 \dots$,” and (monadic) predicate terms “ $F_0, F_1, F_3 \dots$.” Some possible instances of PC1–PC3, respectively, are the following:

$$\begin{aligned} &(\forall x_0 (F_1 x_0 \rightarrow F_1 x_0) \rightarrow (F_1 c_5 \rightarrow F_1 c_5)) \\ &(\forall x_7 (F_2 x_7 \rightarrow F_8 x_7) \rightarrow (\forall x_7 (F_2 x_7) \rightarrow \\ &\quad \forall x_7 (F_8 x_7))) \\ &(F_4 f_{88} (c_{17}) \rightarrow \forall x_3 (F_4 f_{88} (c_{17}))) \end{aligned}$$

As with the language of propositional logic, there will be infinitely many such axioms, most of which will be much more complicated than these three. The value of these axiom schemas is that we don’t have to worry about the impossible task of specifying these axioms individually, since the schemas allow us to capture them all in one fell swoop.

Axiom Schemas in Mathematics

Moving from logic to mathematics, axiom schemas are also indispensable in the formal study of axiomatic theories. However, it is perhaps worth noting that the techniques and practices of most working mathematicians are typically less emphatically formal than those of logicians. Two well-known examples are worth considering, however. The first is from first-order Zermelo–Fraenkel set theory and is known as the *axiom schema of separation*. One possible formulation of this axiom schema is as follows:

$$\forall s_0 (\exists s_1 (\forall s_2 ((s_2 \in s_1) \leftrightarrow ((s_2 \in s_0) \wedge \phi))))$$

Here, the metalinguistic variable “ ϕ ” can be replaced by any formula in the language of first-order set theory. In practice, “ ϕ ” will typically be instantiated with a formula in which the variable “ s_2 ” occurs free. Hence, the formula instantiating “ ϕ ” will represent some condition that the values of “ s_2 ” must satisfy, thus *separating* out from the sets that are the values for the variable “ s_0 ,” those subsets whose members all satisfy the condition in question. For example, an instance of the axiom schema of separation is

$$\forall s_0 \exists s_1 \forall s_2 \left((s_2 \in s_1) \leftrightarrow \left((s_2 \in s_0) \wedge \forall s_3 \left((s_3 \in s_2) \rightarrow \sim \exists s_4 (s_4 \in s_3) \right) \right) \right)$$

This instance of the schema is an axiom telling us that there is a (possibly empty) subset of every set where the members of that subset are such that their own members do not have any members themselves.

Another indispensable axiom schema shows up in formal theories of arithmetic. This is the axiom schema of induction, telling us that if zero satisfies some condition—that is, the value of the metalinguistic variable “ ϕ ”—and any number satisfying this condition implies that its successor *also* satisfies the condition, then all numbers satisfy the condition

$$\left(\phi(0) \rightarrow \left(\left(\forall x_0 (\phi(x_0) \rightarrow \phi(x_0 + 1)) \right) \rightarrow \forall x_0 (\phi(x_0)) \right) \right)$$

For example, here is one instance of the axiom of induction where the condition specified by the wff instantiating the metalinguistic variable, “ $\phi()$,” is the condition $\sum_{i=0}^{()} (i) = \frac{i(i+1)}{2}$ (I have omitted the numerical subscripts on the bound variable “ x ” for readability):

$$\left(\sum_{i=0}^{(0)} (i) = \frac{i(i+1)}{2} \rightarrow \left(\forall x \left(\sum_{i=0}^{(x)} (i) = \frac{i(i+1)}{2} \rightarrow \sum_{i=0}^{(x+1)} (i) = \frac{i(i+1)}{2} \right) \rightarrow \forall x \left(\sum_{i=0}^{(x)} (i) = \frac{i(i+1)}{2} \right) \right) \right)$$

Again, the impossible task of individually specifying every numerical property that we might want to deploy in an axiom of induction is sidestepped thanks to the use of an axiom schema.

Concluding Remarks

Throughout this entry, the notion of a metalinguistic variable has been ubiquitous. Indeed, the distinction between the *object language* (e.g., the formal languages of propositional logic, the predicate calculus, and first-order set theory) and the *metalanguage* (here, the language of English supplemented with symbols like the Greek letters used as variables) is arguably the essential technical distinction underlying the use of axiom schemas. The point of this distinction was made vividly by Tarski (1983, chap. 8) in his proposal of the *T-schema*, an axiom schema for axiomatizing the concept of *true sentence* in a formal language:

For any ϕ , “ ϕ ” is true if and only if S

Here the corner quotes surrounding “ ϕ ” indicate that we are *not* talking about what it takes for “ ϕ ” to be true, as this symbol is only a metalinguistic variable over sentences in the object language, not an actual sentence in the object language. Meanwhile, S is a variable representing the *translation* of the value of “ ϕ ” into the metalanguage. As Tarski helped to make clear, the distinction between the object language and metalanguage is needed to avoid *semantic closure*, in which the language has expressions that refer to other expressions within the same language. As MacFarlane makes clear on pages 61–65 in his textbook, avoiding this kind of closure, and thus avoiding the so-called *semantic paradoxes*, is another primary motivation for making use of axiom schemas in logic and mathematics.

AXIOMATIC THEORY

In ancient Greek philosophy, axioms were first principles that required no reasoning or justification as they could be believed to be immediately apparent. In modern philosophy of science, at least in the *non-statement view* of metascientific structuralism, axioms are part of a formal reconstruction of a theory which, according to the founders of this movement in philosophy of science, abated the longish discussion in the community of the translatability between observational and theoretical terms and statements. This entry traces the development of axiomatic theory from its origins, describes the elements of the theory and its models, and concludes with a note on its applications in various sciences.

Observational and Theoretical Statements

Rudolf Carnap, in his *Philosophical Foundations of Physics*, still found “the distinction between what may be called . . . empirical laws and theoretical laws” [. . .] “one of the most important distinctions between two types of laws in science,” empirical laws referring to “properties directly perceived by the senses” such as “blue,” “hard,” “hot” from the point of view of the philosopher, or properties “that can be measured in a relatively simple way” (Carnap, 1966, p. 225). But the distinction between properties perceivable by the senses and those measured in a *relatively* simple way is not really clear-cut, and the simplicity of a measurement is not clearly definable either. Moreover, the problem persists that

theoretical laws were formulated in theoretical terms, whereas empirical laws were formulated in observable terms.

Hence, it became necessary to introduce so-called correspondence rules for a translation between the two kinds of terms, for instance between the temperature of a gas as an observable in Carnap’s wider sense—temperature being a term of the observational language—and the mean kinetic energy of its molecules as a theoretical term in the theoretical language, or to give an example from the social sciences, between the answer to a question such as “How much confidence do you have in President Joseph Biden?” with possible answers “a lot of confidence, some confidence, not too much confidence, no confidence at all” as an observable and the propensity to cast a vote in favor of President Biden, the latter being a theoretical term, because not even the interviewee would be able to give a numerical value to their probability to vote in the oncoming election for the incumbent candidate. The latter example shows that what is often called the operationalization of a theoretical term can be merely arbitrary with the help of one or more such observable answers to a related question. Another collection of possible answers, for example, 11 or 10 or 5 instead of 4 possible answers, would lead to another operationalization result. To keep this example, one could even argue that one needs some other theory relating the propensity to vote for a certain candidate to the propensity to give certain answers to certain questions, such that correspondence rules would be necessary to link attitudes, voting, and answer propensities to answers given in a certain interview situation.

The so-called syntactic view of theory structure uses these correspondence rules to *translate* between observational and theoretical language (but this kind of *translation* is obviously not of the same kind as a translation between, say, English and Chinese).

The first but incomplete attempt to overcome the dichotomy between observable and theoretical terms was made by Frank P. Ramsey in what is called the *Ramsey sentence of a theory* (also referred to as a *Carnap sentence*), which eliminates the theoretical terms from a theoretical law. If the interpreted theory

$TC = T(\tau_1, \dots, \tau_n) \wedge C(\tau_{i_1}, \dots, \tau_{i_k}; \omega_1, \dots, \omega_m)$ is the conjunction of all theoretical postulates T (all of them formulated in the theoretical language) and all necessary correspondence rules C (these in turn using terms from both languages, observational and theoretical), then it is possible to replace the theoretical terms τ_{i_j} which occur in the correspondence rules (with its observables $\omega_1 \dots \omega_n$) with new variables ϕ_i and replace the interpreted theory with its Ramsey sentence, which postulates that $\exists \phi_1 \dots \exists \phi_k TC(\phi_1, \dots, \phi_k, \omega_1, \dots, \omega_n)$ now claims that substitutions exist for the uninterpreted theoretical terms.

This elimination, however, leaves open the question of how theories are linked together, as in the voting propensity example above. The solution came with the so-called semantic view of theory structure, which introduced set-theoretical entities instead of linguistic ones; this was John D. Sneed's effort to define the logical structure of a theory with set-theoretic predicates instead of speaking about statements whether they are observational or theoretical (which is why this view on theories is called the *non-statement view*).

Elements of the Theory and Its Models

The structuralist program, which builds upon Sneed's work, is centered on the definition of theory elements. A *theory element* is a mathematical structure consisting of a theory core and a set of intended applications, whereby the theory core describes what can be said about the intended applications of the theory core. Theory elements are usually one or a few laws within a scientific discipline, for instance Hooke's spring law (HSL) or classical particle mechanics dealing with masses, forces, velocities, and so on, as the origin of structuralist consideration was clearly within physics, mainly because in physics mathematical formalizations have a long tradition dating at least as far back as Newton and Kepler.

The theory core is a set-theoretic predicate which is typically defined as follows:

T is a theory element if and only if there exist sets of partial potential models M_{pp} , of potential

models M_p , of models M , of constraints GC , of links GL and of intended applications I such that

$K = \langle M_{pp}, M_p, M, GC, GL \rangle$ is a theory core,

$T = \langle K, I \rangle$ is the theory element and

$I \subseteq M_{pp}$

The set of partial potential models M_{pp} is defining its elements x as another mathematical structure listing all terms which are necessary to speak about the theory in question. In the case of Hooke's law, this list contains a finite set of springs S , a finite set of identical pieces of metal or some other material which can easily brought into an identical form (*weights*) W , three functions $n(w, s)$, $l(w, s)$, and $k(w, s) = l(w, s)/n(w, s)$ yielding the number of weights in a collection w of these weights hanging from a spring and the length of the extension of the spring caused by the weight collection w , whereas $k(w, s)$ is the outcome of an experiment with spring s and weight collection w . In this simple example, the difference between M_p and M_{pp} is very small; it consists of the observation that for small lengths of the extension of the spring, k does not depend on w . The terms s , w , n , l and k can each separately be defined without knowing anything about mechanics: Springs and weights can be identified as such, weights in a collection can be counted, extension lengths can be measured, and the quotient k can be calculated. It is only the assumption that k does not depend on the size of the collection of weights but only on the characteristics of the spring that allows for a redefinition of $k(s) = l(w, s)/n(w, s)$ and separates partial potential models from potential models, as the full model is a potential model for which the axiom of Hooke's spring law holds, namely that for all collections of weights and for each spring which is not extended beyond a certain maximum extension $l_0(s)$, $k(s) = l(w, s)/n(w, s)$ is constant and independent on the collection of weights, from which it follows that $l_0(s)$ and $k(s)$ can be considered as device constants. Moreover, as the experimenter will perhaps use their hands to extend the spring, they will feel Carnap's property directly perceived by the senses as it costs more and more effort the longer the extension is. Hence, the

experimenter will assume that there is a monotonically increasing function between their effort and the extension, and it seems reasonably to define this function as a linear function—the HSL-theoretical term *force*—and use it to make this effort quantitatively measurable as proportional to the length of the extension.

The difference between observable terms and theoretical terms is redefined in a straightforward manner as *theoreticity*, always in reference to a theory in question and not an absolute feature of a term. Counting weights, measuring lengths, and dividing numbers necessitate their own theories but not a theory of springs and weights. Hence, the force and the device constants $l_0(s)$ and $k(s)$ are HSL-theoretical terms, all the others are not (and perhaps the value of $l_0(s)$ depends on the accuracy with which $l(w, s)$ and consequently $k(s)$ is measured; the precision of $n(w, s)$ is a lesser problem in this idealized experiment).

Constraints, Links, and Theory Nets

Constraints of a theory collected in the set *GC* are about restrictions to its applicability; in the simple example above, this could be the constraint that all pieces are of the same volume, form, and of the same chemical composition (i.e., the theory would not apply to pieces some of which are balls whereas others might be extremely flat but with the same volume) and that these three features are constant over time (i.e., the theory would not apply to identical pieces of ice which might melt away over time).

Links of a theory element collected in the set *GL* connect it to other theory elements; in the simple example above, volume and chemical composition are used as if they were properties “that can be measured in a relatively simple way.” But to determine the chemical composition of a weight hanging from a spring, some chemistry is necessary; and even to determine the equality of the volume of several metal balls it is necessary to measure their diameters in cm and to assume that the same formula from geometry yielding the volume in cm^3 applies to all of them. Hence, in a way the theoretical links replace the correspondence rules of earlier approaches, but with the important difference that the observational part of a correspondence rule is free from

any theory. Links are defined as sets of tuples of terms which connect correspondent terms of the two theories in question. In the example above, there is the term l denoting the length of the extension of the spring in the theory of Hooke springs and the term l^* in geometry, both of which map to integer numbers (multiples of a certain small unit length).

Not only can two theories be linked together, but theory nets can be built that potentially encompass wide areas within and across disciplines. Thus, the discussion about reducing an *observational law*—say the law $p\nu = kT$ connecting pressure p , temperature T , and volume ν of a gas—can be restated in terms of a theoretical law

assuming that $p = \frac{2E}{3\nu} = kT$, where the pressure is

related to the mean kinetic energy E of the gas molecules. This also ends the discussion about *reductionism* as the assumption that social science could somehow be *reduced* to psychology, the latter to neurobiology, and further to chemistry, and still further to particle physics; instead theoretical terms of a theory in one of these disciplines could be linked to (instead of reduced to) theoretical terms of another discipline.

In the social sciences, most theories have many more terms than in the simple example from classical mechanics. Nevertheless, a structuralist reconstruction of middle-range theories is possible, too. A theory, call it AOF, about attitude or opinion formation, containing terms such as the propensity to vote for a certain candidate or party and the influence of communicating attitudes between citizens certainly has a number of AOF-theoretical terms—for example, $\alpha: P \times T \rightarrow R$ such that $\alpha(p, t)$ is the position of person p at time t on a left–right scale and $\delta: P \times P \rightarrow R$ —such that $\delta(p_1, p_2)$ and $\delta(p_2, p_1)$ are the movements of Person p_1 and Person p_2 on the left–right scale after they met each other and they have discussed their attitudes toward the candidates and parties running in an oncoming election. In an application of such a theory, the distributions of votes cast for candidates and parties would be observable as AOF-non-theoretical terms (as these could easily be counted) and the distribution of answers to questions like the one cited above (“How much confidence do you have in President

Biden?”). A theory about measuring attitudes with algebraic algorithms such as principal component analysis (PCA) could be linked to AOF, and this intertheoretic link would help to reinterpret the PCA-theoretical terms α and δ as AOF-non-theoretic terms. The function that connects $\delta(p_1, p_2)$ on one hand with $\alpha(p_1, t)$ and $\alpha(p_2, t)$ on the other hand would then be the actual AOF-theoretical term. The theory would have to provide axioms that govern the development of the individual attitude changes and of the distribution of attitudes over a large population in which persons meet each other under certain conditions. Some of these conditions of meeting might be *observable*, in other words AOF-non-theoretical, whereas other such conditions—for instance preferences to discuss with other persons depending on the known or guessed attitude difference between two persons who meet occasionally cannot be directly observed. A few attempts to reconstruct theories of opinion formation have already been made and show the difficulties of such attempts, which are mainly caused by at least two of the big differences between the systems physical theories are about and those which social scientists deal with: The heterogeneity of the *particles* social scientists have to take into account and the fact that human beings, unlike physical particles, can communicate individually and change the internal state of other individuals. Hence, theory nets in economics, and the social sciences generally, but also in the environmental sciences with their extremely complex systems will be much more widespread than in physics. (Balzer, Moulines, and Sneed, the founding fathers of the structuralist program, in their 1987 book themselves reconstructed only pure exchange economics with an intended application that they described as “some specific village at some specific time” (Balzer et al., 1987, p. 161) and did not continue their approach to the formulation of constraints or links.)

Applications in Various Sciences

Since the late 1970s, the method of formally reconstructing theories according to the *non-statement* view has been applied to various (pre-formal) theories in various disciplines. As the movement started within physics, the first candidates to be

reconstructed were taken from classical physics, thermodynamics, quantum mechanics, chemistry, biology, medicine, neuroscience, psychology, economics, management, and the social and political sciences. It is not surprising that the density of publications in these disciplines decreases along this list, and it is particularly striking that the acceptance of the *non-statement view* seems to have been greater in German- and Spanish-speaking countries than in English-speaking countries (although English as a publication language still prevails). The disciplines at the end of the list above are much less formalized and quantified than those at the beginning of the list; hence the late and sparse introduction of theory reconstruction into studies of organizations and large social and political systems is understandable, as the reconstruction of a theory that was formulated mathematically long ago is much easier than that of a verbally formulated theory with all its ambiguities. With the emergence and continued development of computational social science, this situation will certainly change in the years to come.

BELIEF REVISION

The stability and malleability of belief is the concern of belief revision. As with most theoretical language, belief and its revision have multiple meanings depending on purpose, context, and logic, so any case must define its terms and their scope. This entry focuses on belief revision within the context of scientific reasoning.

Stakeholders are divided by whether they orient belief in the realm of cognitive (knowledge and reasoning) or affective (emotions, attitudes, values, and spiritual belief). The topic of belief revision need not address the stability or malleability of the world one is believing in but simply the dynamics that influence belief persistence, adjustment, or abandonment. Although individuals may revise beliefs pragmatically, beliefs in the sense of scientific theory or a computer software's logic would require a deliberate strategy reflecting a philosophy of science. For instance, Karl Popper (1902–1994) would reject a prototype model if any part diverged, but Willard Van Orman Quine (1908–2000) would revise or *fine-tune* the prototype until all parts became congruent.

Defining Belief and Its Revision

The revision function depends upon the defined scope of the belief, the logic used to determine doubt or confidence, and the epistemic aims and values regarding the belief. Belief may represent *propositions of truth*, justified by rational argument

to produce knowledge. Belief may also suggest the degree of confidence in the proposition (faith) or it may provide the justification for other beliefs (theory). Belief may denote a pattern of interpretation (habits of mind) or judgment (ethics and morals). A belief system is one in which truths form a coherent framework of understanding (ideology); that is, an integrated, coherent protocol for making decisions (priorities), predictions (hypotheses), or solving problems (algorithms).

Theories Explaining Belief Revision

The first definition above is the standard used in *scientific reasoning* and especially in computer programming. Each coded statement contributes a belief to the mechanical logic. These statements reduce the complexity of a scenario to very small increments, forming a cohesive set of responses to new information. Advanced programs are called *artificial intelligence* if they *learn*, that is, if they can change their own coding. Belief revision thus refers to advanced coding logic for designing computational programs. Apart from the technicalities involved, this discourse informs analytic philosophy, which will symbolize propositions in transformational language akin to algebra.

If each belief serves to scaffold further beliefs, there is a foundation required to reach complex heights. The *belief set* is a closed set of propositions under examination, while *belief base* can examine separate propositions that are elements of the base and can tell the difference between those that are explicitly stated and those that are

a logical extension of the explicit beliefs. The primary goal of such a *foundation theory* is to discover truth, and thus a faulty premise casts doubt on the entire code sequence. This coding logic will identify an erroneous proposition and then either accept it (expansion), remove it (contraction), or both add something and take something else away (revision). It is a syntactic approach, akin to using syllogism for deductive reasoning. By contrast, a *coherence theory* is a synthetic approach, accepting new propositions for their logic in maintaining the meaningfulness of the whole framework; in other words, *verisimilitude*. Stability of the network of decisions is more important than semantic integrity, so the existing belief structure is not revised so much as its applications. A computer program example would be the apparently intuitive helpfulness of online search engines to provide advertisements consistent with topics related to your own history of links. The purpose of the algorithm is to generate all links consistent with what appears to be your consumer interest; no ideology is at risk for the computer by adding more search items. As long as the additional information is consistent with your own belief about the purpose of being online, you do not revise your belief; however, once the cost of these additions is too great, such as when the ads are distractingly animated and intrusive, you may revise your belief. According to foundation theory, you might abandon that browser or online shopping if you conclude the practice is wrong, but according to coherence theory, you might simply work around the ads if they are tolerable, or the stability of your habit takes on greater value than the dissonance of incompatible behavior.

Experimental studies of belief revision may be structured in series with multivariate analyses used to identify effect sizes for a range of possible influences. The formulas used in the statistical packages are themselves the source of inquiry now that computation can occur so quickly. Repeated measures of cognitive learning outcomes in schools are used to monitor cognitive change interpreted according to pedagogical theory.

Belief Persistence

One reason a belief is held in the face of contrary evidence is simply habit for individuals and the

momentum of a complex network for organizations. Habits are automatic, whereas belief revision requires deliberation. There is also an emotional dimension of enjoying the predictability of customary beliefs and not trusting that the work and discomfort of extinguishing the old ones will be adequately compensated by a better future. Yet another reason beliefs do not change is that memories are faulty at best, it being impossible to retrieve all details of arguments that lead to confidence in the incumbent decision. Also, individual belief systems are fraught with inconsistencies, and people often will tolerate beliefs that do not seem to be aligned. For instance, one can wholeheartedly agree with the need to buy from independent local businesses but will nonetheless search out a bargain at a distant warehouse store.

Many beliefs about the world are formed intuitively at a young age. Teachers must diagnose their students' knowledge base, including misconceptions, in order to design instruction that prompts a more enlightened understanding and assessment that measures the degree of confidence in the new perspective. In this way, learning can be construed as a revision of belief. A particular challenge is posed when the academic objective is dispositional; that is, when students are expected to become more tolerant, frugal, democratic, generous, or healthy. Meanwhile, the aforementioned factors of habit, memory, comfort, and purpose conspire to maintain false beliefs or disbelief.

Belief profiles have been found to correlate with patterns of behavior and conceptual change, and thus belief revision is of interest to those hoping to influence change as well as those simply curious to understand the phenomenon. Given their individual conventions regarding the concept of belief, there are different fields of inquiry concerned with belief revision, for example, education (nature of teaching and learning), psychology (existential crises; self-efficacy), religion (conversions; hermeneutics), business (market analysis; organization management), mathematics (proofs; inferential statistics), science (empirical justification), and computer programming (artificial intelligence).

Many theories have emerged out of interest in belief revision. Thomas Kuhn (1922–1996) described a *paradigm shift* after which a revolutionary idea is

widely assumed to be true, for example, evolution or climate change, each of which has substantial empirical evidence to support it. The correlation for personal beliefs would be the loss of faith after some traumatic event, for instance, one's belief in God or one's trust in banks or one's commitment to marriage. The result is an existential crisis, a conversion to a new belief system, or perhaps agnosticism; that is, not knowing what is true, or perhaps an antagonistic stance such as atheism. Holocaust survivor Viktor Frankl (1905–1997) developed *logotherapy* to explain the sudden deaths of prisoners even when circumstances had not changed. He concluded that all people search for meaning in their lives, a useful construct in mental health.

Cybernetics is a system theory concerned with the dynamics of interdependence. While associated with mechanical or nonhuman systems, the principles of interaction apply to social contexts, especially regarding feedback, whether cognitive or affective. Conflict resolution techniques are a result, making the case for interrupting cycles of violence in any scale, such as within families or between countries. In such matters of diplomacy and legality, terms of formal agreements between parties will specify behaviors associated with target beliefs about their identities and status, given that in any social system there is a continuously challenging landscape of problems with sharing resources and power. Both what is believed and how it is believed will influence the stability of the relationships which are maintained on the basis of continual interaction with trusted sources of information. Open communication is blurred by tactics of silencing voices and withholding or distorting information and of limiting sources to an *echo chamber* that accepts only that which conforms to one's belief.

BIG DATA

Our current age is often referred to as the era of *big data*. While the term has become increasingly popular in the last 10 years, the concept is now used in a wide variety of ways, often without referring to an acknowledged technical definition of the concept. In fact, an agreed-upon and technical definition can be argued not to exist, and the term *big data* is mainly used to refer to broad and general tendencies related to a rapid increase in the data collected in various domains and the accompanying need to develop and employ new methods of analysis in order to make sense of such data. These methods of analysis connect big data intimately to data mining, artificial intelligence (AI), and machine learning.

Big data has become a ubiquitous phenomenon, and it is applied to domains such as research, business intelligence, social networks, health care, crime prevention, and anti-terrorism. Data is routinely described as the “new oil,” and in parallel with the historical discovery of other precious

resources, the quest to drill, mine, and refine it is both intense and characterized by competition, rapid development, and private sector innovation. Big data carries a number of actual and potential benefits, but it is also related to a number of ethical challenges. Many are related to the nature of the data employed, some relate to a purported blind and dangerous faith in quantitative data and algorithms as the solution to and source of insight in *all* aspects of human lives, and some are mainly related to the use of algorithmic decision-making in general. The next section of this entry presents an expanded definition of big data, followed by an exploration of the philosophical basis of the concept and its roots in the quantitative and empiricist approach to knowledge. Before concluding, the entry offers a discussion of the ethical considerations surrounding the growing applications of big data.

Definition

Big data refers to a development toward generating and gathering increasing amounts of data at increasing speeds, while the data is structured in heterogeneous data sets. The data in question can, for example, be social and personal, or related to industrial processes or scientific measurements, and several sources and types of data are often connected in large data sets.

Although *data* is of course a key component of big data, the tools and techniques used to store, manage, and analyze the data are also integral parts of the concept. The problem with the data sets handled in big data is that traditional methods of storage and analysis are insufficient. Distributed storage systems and cloud computing are used for storing and managing the data. Data mining and machine-learning-based AI have become terms intimately associated with the analysis of the large data sets. The entire chain of generating, gathering, storing, and analyzing data is included as part of what is referred to as *big data*.

Data in isolation—gathered and stored—has limited potential for positive or negative consequences. It is through the quest to derive value from the data that, for example, benefits in business intelligence and concerns over discriminatory practices arise. The term *big data* is now used by

both data and computer scientists, social scientists, and the general public, and the latter two groups often refer to a general and nonspecified concept without referring to particular forms of database management or specific machine learning techniques.

The techniques used to analyze the data are not entirely new, and these stem from earlier academic work in AI and statistics. However, the volume of today's data sets has mainly become a reality through private corporations focused on gathering and using data to provide various services, and this has led to a situation in which much development is done outside of academia. Although private companies are important for developing big data techniques, government and other public institutions are important secondary beneficiaries. There is now a growing tendency for government agencies to use big data in order to, among many other things, prevent crime and terrorism, find effective pandemic responses, and both discover fraud and automate decision-making in social services.

Philosophical Foundation

As data is analyzed in order to answer certain questions, or achieve a set of goals, some philosophical assumptions are inevitably involved. These *can* be made explicit, but far more often, as big data is applied to solve issues of importance for businesses and society, the assumptions remain implicit. One reason is that a lot of the techniques are developed and applied in nonacademic settings, but another important reason is that proponents of big data have repeatedly argued that big data is *not* based on theory or ideology. One of the major causes of disagreement over the implications of big data revolves around the possibility of achieving neutral and objective science through analyses of raw data and partially autonomous AI.

Scientific and other applications of big data are characterized by a multitude of approaches, and in the following a *typical* (but not the only possible) approach is described. By removing the human scientist from the equation, it is argued, true objective science has finally been realized. Such claims disregard the nature and origin of the data, and that data in itself is not neutral. The

various choices related to how data is gathered, which variables are collected, how data is coded, and so forth, by necessity involve a set of choices resulting in data that is a *model* of reality and not an accurate reproduction of it. Also, human beings are heavily involved in the creation of the algorithms used in the analysis of data, decisions about when and how to use big data solutions, and also in choosing how the results are interpreted and utilized.

Big data is based on a quantitative and empiricist approach to knowledge, in which observable phenomena are seen as the basis of knowledge. As machine learning methods have become increasingly advanced, some even argue that human interpretation is no longer an integral part of deriving insight from these observations. Furthermore, *more* data is seen as conducive to more knowledge, whereby observations both strengthen the results of the analysis *and* improve the tools of analysis as data is used to train and further develop machine learning algorithms.

As data is gathered and fed to the computer for analysis, the intent is that AI tools sift through it and uncover interesting patterns in the data which are not identifiable directly by humans or through traditional statistical methods. This process is referred to as *data mining*. Big data is thus usually characterized by inductivism and the idea that we blindly approach data in order to identify patterns and develop theories about dependencies and causation. In practice, however, human beings are necessarily involved in a dynamic process in which initial results from the analysis are examined and used to guide and shape further analysis. Such a process would be more accurately described as a combination of the deductive and inductive approaches, at times referred to as an *abductive* or *retroductive* approach.

Big data as applied to human phenomena is often based on a behaviorist approach, in which observable phenomena and actions are emphasized over, for example, cognitive phenomena and interpretation. When an individual's subjective experiences and evaluations constitute the data analyzed, the goal is likely to be how this translates into actions, and how various variables are connected, rather than a deeper understanding and explanation of what goes on inside people's heads.

In short, big data is philosophically closer to the natural sciences than the social sciences and humanities. The knowledge and insight produced by big data can thus be argued to constitute a part of the answer when human phenomena are examined, and not a complete picture. In order to explain and understand *why* the patterns discovered occur, and how the phenomena and correlations described are actually experienced, human scientists, other methods of analysis, and other forms of data are still vital parts of making sense of the world as it appears through the results produced through big data.

Ethical Considerations

Big data is a major part of much contemporary debate about surveillance, privacy, social networks, and liberty. Although not directly related to big data as *large data sets*, such debate is clearly related to some of the more prominent applications of the general phenomenon of big data understood as large data sets combined with AI for analysis. In this section, the discussion narrows in on *social* and *personal* big data, since data related to individuals and their social relations is the most obvious cause of concern.

A key concern related to big data is a purported lack of transparency and difficulties of explaining the results of AI-based analysis of data sets. Many of the purported benefits of big data are incontrovertible, but an opaque process of analysis often likened to a "black box" creates a situation in which unintended consequences often go unnoticed. For this reason, much research on AI is now focused on creating *explainable AI* because this is required for securing transparency and ensuring that big data and AI are developed and deployed in an accountable and responsible manner.

Because big data is often based on historical data, its use can perpetuate and even obfuscate structural racism, sexism, and other forms of inequality. For example, if a bank employs an algorithm for determining who should receive a loan based on historical data, the models trained on this data will perpetuate historical bias related to, for example, race and gender. Furthermore, although we know that human beings are biased, some argue that machines are *not* biased; therefore, unless the algorithms are audited and

developed in order to foster explanation, discriminatory practices may go unnoticed and even become legitimized.

Privacy and surveillance are other concepts often related to big data, as the generation and gathering of data can be perceived as a form of surveillance. Concerns relate to a violation of rights to privacy in general, and to more insidious phenomena, such as the combination of large numbers of data points from different databases in order to create highly detailed personality profiles. This allows actors to influence individuals more effectively than they could otherwise have done and could thus be construed as inimical to liberty and independence. Such influence relates to all sorts of behavior, including political behavior and government efforts to exert social control.

Whereas the aforementioned use of personal data often involves efforts to market and sell products and services more effectively, the societal consequences of big data are also a cause for concern. Particularly in relation to social media, some authors have shown how big-data-based personalization might allow actors to influence individuals' perceptions of the world (trap them in "filter bubbles" where people are increasingly being exposed to what they *want* to see), influence how people associate and relate to each other (and create "echo chambers" in which they associate only with like-minded people), and thus contribute to societal polarization, which is a growing concern.

In contrast to the preceding challenges, the benefits derivable from big data can potentially help improve individuals' lives and alleviate and solve important social problems. For example, preventing crime and terrorism is clearly a good thing and can easily be argued to warrant the sacrifice on some privacy. The same applies to using big data in health care, where it is used to improve the understanding of diseases and interventions and for more effective diagnosis. The purpose of highlighting the causes for concern mentioned above is simply to show that while big data is highly effective and provides a plethora of new opportunities in all domains of society, it is important to include perspectives from ethics and the social sciences in the development and deployment of big data projects.

Conclusion

While big data is arguably a continuation of a long quest for more information and better methods of analysis, recent developments related to the massive amounts of data gathered from various devices such as household appliances, smart electricity meters, global-positioning-system-enabled devices and other devices with a variety of sensors, and social media suggest that it is reasonable to describe Big Data as a new and important phenomenon. The amount of data has increased rapidly, and even if the machine learning techniques used are not entirely new, they are now trained on far larger data sets than before, which leads to increasingly useful results and a renewed interest in research and development.

Big data is used in all domains of modern societies, and the benefits it provides are substantial. These include, among other things, benefits in terms of scientific advancements, improved business intelligence and analytics, new tools and methods for law enforcement, innovation in health care, and new ways for people and societies to connect, communicate, and share information.

At the same time, there are important ethical concerns raised by big data, which include invasions of privacy, the non-neutrality of data and discrimination, societal effects of social networks, and the use of big data to exercise political influence and control. Those in possession of large data sets gain power and the means to influence others more effectively than ever before.

BIOCHEMISTRY, 19TH CENTURY

The field of biochemistry has a long-standing history of immense contributions to the progress of medicine. Notwithstanding, biochemistry has attracted less attention than the other biomedical sciences. Much of this can be attributed to the fact that as a separate entity it is rather young when compared with the likes of anatomy or physiology. Before 1750, biochemistry was not a full-fledged theory in its own right. It did gain a measure of respectability as its own discipline, however, in the later part of the 19th century and would come to fruition thereafter.

Although a strong association can be traced between biochemistry and organic chemistry, the history of biochemistry has received scant coverage within the history of chemistry generally. This is perhaps because biochemistry was once regarded by chemists as a lesser subdiscipline or as a part of medicine. In its broader sense, biochemistry can be regarded as the study of living matter and its chemical composition as well as of the biochemical processes essential for the maintenance of growth and vital life activities. This entry aims to examine the various developments within the sphere of biochemistry in the 19th century that were important to its subsequent emergence in the 20th century. Significant contributions by eminent scientists, such as the discovery of the activity of

yeasts in alcoholic fermentation, discovery of the first enzyme, and the classification and nomenclature of the enzymes, were all crucial leads for the future generations of biochemists. In this phase, biochemistry was mainly concerned with the study of chemical reactions taking place within living cells (both in microorganisms and in humans).

Roots of Biochemistry: An Overview

The roots of biochemistry can be found in 19th-century studies of organic chemistry, animal chemistry, and physiological chemistry. It was already found by then that the chemistry of living and nonliving materials was markedly different. In the 1830s, it was thought that the jellylike homogeneous substance, protoplasm, present within the organisms was responsible for carrying out most of the vital activities of biosynthesis, respiration, and intracellular food breakdown (metabolism). However, this general belief did not find support from such eminent chemists as Justus von Liebig (1803–1873) or Ernst Hoppe-Seyler (1825–1895). Although the hydrolytic enzymes such as pepsin, maltase, and amylase were known to the scientific world at that time, they were not considered to be acting within the cells. Eduard Buchner in 1897 perhaps performed the single most significant experiment that commenced the study of biochemistry. He prepared a cell-free yeast extract which he named zymase and observed its efficiency in fermenting glucose into ethanol and carbon dioxide. He later went on to receive the Nobel Prize (in 1907) for his discovery of cell-free fermentation and contribution to biochemical research. Zymase was regarded by Buchner as a single enzyme; however, this was soon disproved by others and was found to contain several other enzymes. Nonetheless, Buchner's work discredited the protoplasm theory and confirmed fermentation as a chemical process. Also, the presumed differences between the catalytic activities of the intracellular enzymes and the extracellular hydrolytic enzymes were found not to exist.

The French chemist Louis Pasteur (1822–1895) started studying the alcoholic fermentation of sugar by yeasts. He went on to conclude that the fermentation of sugar to alcohol is carried out by a vital force called *ferments*, present within the yeast cells, that can only function inside the living

cells. He further went on to clarify that fermentation was not associated with the putrefaction or death of the cells but rather was correlated with the organization and life of the yeast cells. In 1833, the first enzyme, called *diastase*, was discovered by the French chemist Anselme Payen, and in 1878 the German physiologist Wilhelm Kühne coined the term *enzyme* to describe this process. Nonliving substances such as pepsin was later referred to as *enzymes*, while the term *ferment* was used to describe the chemical processes of the living organisms.

Anselme Payen and Diastase

Payen, the son of an entrepreneur who had started a number of chemical production factories, rose to fame with his discoveries of the carbohydrate cellulose and the enzyme diastase. He had received knowledge of chemistry from his father and later from the likes of Michel-Eugène Chevreul and Nicolas Louis Vauquelin. Payen was promoted to become the head of his father's borax production plant in 1815. Here, he was able to use boric acid (available cheaply from Italy) to prepare borax. With the production costs going down significantly, Payen succeeded in besting his competitors in selling borax. Payen then shifted his attention in studying the sugar production from sugar beets and thereby established a method of sugar decolorization using charcoal. Subsequently, charcoal filters began to be used in gas masks to absorb dangerous organic gases. In 1833, Payen came up with yet another discovery: a chemical derived from malt extract that could catalyze the conversion of starch to sugar. The catalyst was named diastase, the first enzyme to be produced in concentrated form. The pattern of naming the enzyme diastase, as initiated by Payen, is still existent today with enzymes being named with the suffix *-ase*. He also concentrated his research on wood and extracted from it a substance resembling starch. This substance he named *cellulose*, which he could find in abundance in the plant cell walls he studied. Here also Payen became the pioneer in starting a nomenclature of the carbohydrates that would end with the suffix *-ose*. Although Payen was the first to isolate cellulose, it was the American botanist Wanda K. Farr (1895–1983) who ultimately discovered the mechanism of its

production by plants. Many other subsequent inventions used cellulose as a building block. It became the main component in a number of products, including cellophane, celluloid, rayon, collodion, guncotton, nitrocellulose, and other related products.

Louis Pasteur and Alcoholic Fermentation

The first of Pasteur's contribution to the study on microbial activities was in relation to lactic acid fermentation. Pasteur was consulted by a local alcohol producer, a Monsieur Bigo, who was facing serious problems with fermentation. After careful examination of the fermenting liquor under a microscope, Pasteur found that when the fermentation was satisfactory, the globules present were rounded in shape, but when they deteriorated and became elongated, the end product was lactic acid fermentation. There are four general requirements for such work, as suggested by the papers published by Pasteur on lactic acid fermentation. The conditions to be fulfilled include the following: (1) Optimum conditions must be prevalent in order to study the process of fermentation, (2) the substances used should be from the simplest possible source, (3) the appearance of the organism during the process of fermentation should remain constant, which should be confirmed by careful examination under the microscope, and (4) the characteristic fermentation can be produced by even a minute trace of the presumptive cause. In 1857, Pasteur published the first paper on alcoholic fermentation. In accordance with the catalytic theory of von Liebig and Berzelius, the ferment takes nothing from the fermentable material and gives up nothing during the fermentation process. However, when the ingredients were weighed prior to the commencement of, and following, fermentation, it was clear that the yeast cells were taking something from the sugar. The sugar's breakdown into carbon dioxide and alcohol was associated by Pasteur to the living processes, wherein the part of the material for the yeast was provided by sugar. The role of yeast in alcoholic fermentation was affirmed by Pasteur in 1860. In sharp contrast to von Liebig's assumptions, ethanol and carbon dioxide constituted only 95% of the products of fermentation of invert

sugar (mixture of glucose and fructose). The rest of the 5% included cellulose, succinic acid, and glycerol. Thus, Pasteur proved that yeast indeed took something from the sugar which was not returned; hence he claimed that fermentation is a physiological process. Also, Pasteur was able to produce a yeast type from a defined medium containing inorganic phosphate and ammonium tartrate along with sugar. There was no existence of any substance that can be putrefied by oxygen and make sugar unstable, as had been proposed by von Liebig. Thus, the theory that the origin of yeast is dependent on the action of oxygen on the fermentable liquid was refuted by Pasteur. Here, Pasteur has also encountered the problem in differentiating between fermentation by intact cells and by enzymic action. There was a long-standing difficulty around the confusion regarding the difference between enzymic action and fermentation, and Pasteur gave special attention to this issue. He had a particular difference of opinion with Marcellin Berthelot (1827–1907), an eminent figure in the French scientific community. In 1860, around the same time when Pasteur published his alcoholic fermentation paper, Berthelot provided an important account of how sucrose is broken down into fructose and glucose by beer yeast. Earlier, Eilhard Mitscherlich had given accounts on the activity of yeast extract to produce a levorotatory sugar from cane sugar. Augustin-Pierre Dubrunfaut further went on to show that glucose and fructose constituted the levorotatory sugar. In order to refute the views of Pasteur, Berthelot in 1860 described the method of invertase (β -fructofuranosidase) isolation that can break down sucrose. Pasteur was of the opinion that it was the succinic acid produced during the fermentation process that was responsible for the breakdown of sucrose. Succinic acid, however, could not invert sucrose at all in conditions similar to that which is prevalent during the process of fermentation, and inversion was only possible in an alkaline medium. During the interval from 1860 to 1880, chemists had a definite change in stance concerning the activities of the enzymes and the process of fermentation. The findings of Berthelot and Pasteur are thought to have provoked these changes in attitudes of the scientific community toward the biological processes and helped immensely in building up and shaping the field of

biochemistry during its periods of infancy. In 1878, Wilhelm F. Kühne, in order to remove the confusion surrounding the double meaning of the term *ferment*, introduced the term *enzyme* to designate the soluble ferments.

Contribution of Eduard Buchner

Eduard Buchner started his work with Adolf von Baeyer in chemistry in 1884 and with C. von Naegeli in botany. His brother Hans was his special supervisor at the Botanic Institute, Munich. In 1885, his first publication explained the effect of oxygen on fermentation. He received special stimulation and assistance for his research in organic chemistry from the likes of H. von Pechmann and T. Curtius. It was possible for him to continue his studies with the aid of the Lamont Scholarship. With grant aids from von Baeyer, Buchner established a small laboratory of chemical fermentation, where he performed his experiments on chemical fermentations. The rupture of the yeast cells was experimentally studied by him in the year 1893, although the board members of the laboratory believed that this would accomplish nothing. In 1907, Buchner went on to receive the Nobel Prize for his discovery of cell-free fermentation and contributions to biochemical research. In 1897, the experimental design was set up with the production of a cell-free extract from yeast cells. Buchner went on to show that the cell-free extract could ferment sugar. The theory of vitalism received a severe blow when it was shown that the process of fermentation did not require the presence of living yeast cells. He prepared the cell-free yeast extract by a combination of kieselguhr (diatomaceous earth) and quartz with dry yeast cells after pulverizing the dry cells with mortar and pestle. With the cell contents coming out of the yeast cells, the mixture became moistened. Following this step, a press was used for the mixture to be passed through that would result in the production of the *press juice* that contained fructose, glucose, or added maltose. Carbon dioxide sometimes was found to develop. It was found through microscopic analysis that the extract contained no living yeast cells. Buchner believed that the proteins secreted by the yeast cells in their environment were responsible for the fermentation of the

sugars, but later it was confirmed that it was within the yeast cells that the fermentation took place.

Sugar Metabolism and Enzyme Specificity

Toward the end of the 19th century, Emil Fischer emerged as a leading organic chemist who today is regarded as the founder of carbohydrate chemistry. The first ideas about enzyme specificity and its molecular mechanisms were drawn from his studies on sugar metabolism in yeast. A new hexose, mannose, was prepared in 1888 by Fischer and Hirschberger, which at room temperature could be fermented avidly by beer yeast. Yeast was earlier encountered by Fischer when his father had invested in a Dortmund brewery. He used sugars such as galactose, mannose, and glucose to test for the fermenting ability of beer yeast. He found that fermentation was possible for the D-sugars only. Thus, he could separate this form from the racemic mixtures with L-forms. Similar approach was undertaken by Pasteur for the tartaric acids. Subsequently, the osazones and hydrazones of the corresponding L-sugars were characterized by Fischer. Prior to this, Fischer was able to discover the reaction between the sugars and phenylhydrazine, which was later used in deriving the configurations of the sugars. The sugars produce characteristic osazone crystals; this was an important finding since previously the major handicap of sugar chemistry was the problem in obtaining sugar crystals. In line with the shift of Pasteur from chemistry to biology, Fischer, after establishing the sugar configurations and monosaccharide classifications, thought of applying his findings to biological research. To save material, he made use of a very small fermentation tube, since the sugar preparations were often laborious and the experiments needed to be repeated frequently. Until exploited by Fischer, Pasteur's finding about the potential ability of the microbes to discriminate between the L- and D-substrates received little attention. Accordingly, Fischer observed that only the D-forms of the sugars like galactose, mannose, and glucose were fermented by the microbes and not their L-counterparts. Additionally, he found that the different sugars were fermented by different yeasts and their fermentation ability also

varied considerably, which can be largely attributed to their structural characteristics. Fischer in 1894 developed the image of lock and key that formed the basis of enzyme-substrate complex formation, as developed later on by Leonor Michaelis, Maud Menten, and Victor Henri. It is also implicated in the idea of substrate destabilization or transition state stabilization and in the role of selective binding energy—the basis for substrate activation theory by J. B. S. Haldane, enzyme transition state complementarity by Linus Pauling, and induced fit theory by Daniel Koshland. All these eminent scientists have acknowledged the findings of Fischer as the basis for their works.

Kühne and Physiological Chemistry

Wilhelm Kühne joined Heidelberg in 1871 to replace Helmholtz. Here in Heidelberg, Kühne went on to produce some of the greatest discoveries of his life, including the digestion of protein and the chemistry of vision. He continued to work selflessly and enthusiastically in Heidelberg and left a rich legacy in the history of biochemistry and physiology. Besides his mainstream work, his research included a series of miscellaneous studies. Kühne published papers on the origin of hippuric acid, artificial diabetes in frogs, resuscitation of carbon monoxide, poisoned dogs, the cause of jaundice, blood ozone content, occurrence of ammonia in blood, cholera transfer and treatment, and on many other aspects of physiological chemistry, thereby demonstrating his breadth of talents and versatility of interests. Living muscle fiber sarcoplasm was considered by Kühne as a protein-rich fluid whereby clotting of the proteins takes place during heat or death rigor. Kühne observed sarcoplasm fluidity with the accidental finding that inside a single frog muscle fiber, a living nematode could pass through the cross striations by performing active movements. This was when the concept of myosin came to the fore. (Albert Szent-Györgyi, a hundred years later, would study the phenomenon of muscle contraction based on Kühne's myosin discovery.) Kühne then turned his focus to the study of digestive enzymes and ultimately went on to discover trypsin, which can be regarded as a landmark discovery in the field of proteomics research. Besides

discovering trypsin, his efforts also identified a number of protein digestion products. Using a mixture of dog pancreas and beef fibrin, he observed that fibrin solubilized with the concomitant appearance of peptone, leucine, and tyrosine. In a piece of dog small intestine which still had in place the pancreatic duct, similar digestion products could be obtained. The digestive function of pancreatic juice was confirmed, and Kühne found that this activity was different from the role, earlier discovered, that gastric juice performs. At the Naturhistorisch-Medizinischen Verein, Heidelberg, Kühne delivered a lecture in 1876. Here, he went on to introduce the term *enzyme* to designate unorganized ferments such as ptyalin and pepsin. The actions of these substances could already be distinguished from that of the living cells known to contain ferments in an organized specialized form. The pancreatic powerful proteolytic enzyme was termed *trypsin* (the cleaver). Kühne is also credited with the extraction of trypsin and examination of some of its properties. This was followed by a series of other observations in relation to trypsin, such as the fistula-mediated collection of pancreatic juice; protein clotting by this juice; observation of the pancreatic cells that secrete this juice (which undergo a change in form during secretion); and the microscopic observation during rest and digestion of the rabbit pancreas. With Ewald, Kühne tested the activity of trypsin on different animal tissues, being aware of the potential usefulness of trypsin in histology. His outstanding understanding of physiology and chemistry allowed him to bring insights from both to solidify the basis of biochemistry. Trypsin was unsuccessful in digesting some of the tissue elements, and these he was able to isolate as keratinized and collagenous structures. This reignited Kühne's earlier interests in protein chemistry and protein digestion, and with Russell Henry Chittenden he resumed his works on these aspects of protein biology. He had earlier established that proteins and carbohydrates were distinct in their composition by employing alkaline and acid hydrolysis to obtain some of the products of protein hydrolysis that were entirely distinct from that of the carbohydrate hydrolysates. The research was extended by Kühne to make it more physiological and relevant from the biological perspective by using pancreatic and

gastric juice enzymes. Two of the general groups of substances found as the early products of digestion, namely peptones and albumoses, had previously been found by different investigators as products of alkaline and acid hydrolysis of proteins. Eventually, a number of amino acids could be detected. It was quite obvious that Kühne and Chittenden were successful in identifying the sequential nature of intestinal (pancreatic) and gastric digestion of proteins, since the breakdown of proteins could proceed to a certain extent in an acid-trypsin environment and required the alkaline-trypsin environment to proceed further. Knowledge regarding the difference in action of trypsin and pepsin on the peptides has been much extended to the present day and terms such as *antipeptones*, *antialbumoses*, *hemipeptones*, and *hemialbumoses* that were used frequently by Kühne and Chittenden are no longer existent. However, it cannot be denied that these pioneering works are the cornerstone for the field of proteolysis, which has immensely enriched the sphere of biochemistry.

BIOCHEMISTRY, 20TH CENTURY

Biochemistry may be defined as the study of different chemical processes in all living organisms. These processes typically govern all life functions, as for example by controlling information flow through biochemical signaling networks and the intrinsic flow of chemical energy by way of metabolism.

The history of biochemistry spans more than eight centuries. Its origins can be traced to the ancient and medieval societies of China and India, with subsequent advancements made in the Islamic world during the centuries that followed. With the introduction of clinical trials and clinical pharmacology in the modern era, biochemistry had continued to make significant breakthroughs, although it was only in the year 1903 that the term *biochemistry* was proposed by Carl Neuberg, a German chemist, to denote a single interdisciplinary subject combining elements of what hitherto had been two separate disciplines, biology and chemistry. Over the course of the 20th century, biochemistry gradually developed into an essential discipline within the life sciences.

Much research deals with the basic structures and effective functions of cellular components such as carbohydrates, proteins, nucleic acids, lipids, and many other biomolecules, although the study of various natural processes involving close-linked networks rather than those of individual molecules is quickly becoming the focus of biochemistry. During the last half century, biochemistry has succeeded in explaining a variety of life processes, and as a result many disciplines, from medicine to botany, are seriously engaged in biochemical research. Today, it has become the main focus of pure biochemistry to understand how biological molecules actually give rise to the processes that typically occur within living cells, which in turn significantly contributes to the understanding of whole organisms.

Among the vast numbers of many different biomolecules that exist in the living system, most are large, highly complex and molecules (called

biopolymers), which are composed of many similar repeating subunits (called *monomers*). Each of these classes of polymeric biomolecules has a very different set of various subunit types—for example, a *protein*, which is essentially a polymer whose different subunits are selected from a typical set of 20 or more amino acids. *Carbohydrates*, in the form of polysaccharides, are formed by linking monosaccharides or oligosaccharides; *lipids* are typically formed from combining fatty acids and glycerols; and the nucleic acids are formed from the simple nucleotides. Biochemistry also studies the basic chemical properties of the very important biological molecules, which includes proteins with catalytic activities, in particular the hard-core chemistry of the enzyme-catalyzed reactions. Furthermore, the metabolism of specific cell types and the working of the endocrine system have also been quite extensively described. Some other areas of focus in biochemistry include the understanding of the genetic code as embodied in the nucleic acids deoxyribonucleic acid (DNA) and ribonucleic acid (RNA); cell membrane transport; protein synthesis; and the phenomenon of signal transduction, by which a chemical or physical signal is transmitted through a cell as a series of molecular events. Thus, biochemistry as a field of study is highly dynamic and has the potential to continue to develop with time. The following sections discuss some of the significant discoveries and achievements in biochemistry during that period and identify the key subfields and related disciplines that have emerged since the turn of the 20th century.

Major Developments in the 20th Century

Before the turn of the 20th century, the notion was widely held among scientists that living cells were occupied by a substance called *protoplasm*, in whose huge molecules obscure and perhaps incomprehensible chemical changes continuously took place. This view would become discredited when it was discovered that complex cell constituents like the proteins and enzymes could be effectively isolated and carefully crystallized. In 1901, for example, the English biochemist Frederick Gowland Hopkins, with his graduate student Sydney W. Cole, in 1901, discovered the amino acid tryptophan to be a typical constituent of many proteins.

Enzymes

In 1897, the German chemist Eduard Buchner began to study the specific ability of yeast extracts to efficiently ferment sugar despite the absence of any living yeast cells. In a series of critical experiments at his laboratory in Berlin, he found that fermentation of sugar occurred without the presence of living yeast cells owing to the action of some chemical compound in the extract or mixture. He determined this to be an *enzyme* (i.e., a catalytic protein that brought about the fermentation of sucrose), which he named *zymase*. In 1907, Buchner received the prestigious Nobel Prize in Chemistry for his outstanding biochemical research that led to the discovery of typical cell-free fermentation. Following Buchner's example, researchers started naming enzymes according to the kind of reaction they perform in the system. For example, *lactase* is the name of the enzyme that cleaves lactose; *polymerase* is the enzyme that catalyzes the formation of DNA polymers. Many early workers noted that enzymatic activity was typically associated with proteins, but many scientists at that time, including the 1915 Nobel laureate Richard Willstätter, vigorously argued that the proteins were merely the carriers for true enzymes and that these proteins were virtually incapable of performing catalysis. However, in 1926, James B. Sumner clearly showed that urease, a common enzyme, was basically a pure protein and efficiently crystallized it; he again did likewise for another enzyme, catalase, in 1937. Further, the distinct conclusion that many pure proteins can act as enzymes was definitively proved by John Howard Northrop and Wendell Meredith Stanley, who crystallized the three digestive enzymes trypsin, pepsin, and chymotrypsin. For their pioneering efforts Sumner, Northrop, and Stanley were jointly awarded the Nobel Prize in Chemistry in 1946. The critical discovery that enzymes could be effectively crystallized meant that scientists could eventually solve their molecular structures by the technique of X-ray crystallography. This was for the first time done for the enzyme *lysozyme*, which is found significantly in saliva, tears, and egg white, and which is capable of breaking down the cell wall of many gram-positive bacteria. This structure was actually solved by a group of researchers led by David Chilton Phillips, and the

work was published in the year 1965. This crystalized high-resolution structure of lysozyme marked the beginning of the field of structural biology and also led to the effort to understand how these enzymes actually work at the atomic level.

Metabolism

One of the most significant and prolific of 20th-century investigators was the biochemist and physician Hans Adolf Krebs (1900–1981), who made major contributions to the study of metabolism. He himself discovered the urea cycle and later, while working with Hans Kornberg (1928–2019), discovered the glyoxylate cycle and the TCA or citric acid cycle. These significant discoveries led to Krebs being awarded the Nobel Prize in Physiology in 1953, which he shared with another well-known biochemist, Fritz Albert Lipmann, who was in addition the codiscoverer of the essential factor *coenzyme A*. In 1960, the biochemist Robert K. Crane revealed his extraordinary discovery of the phenomenon of sodium-glucose cotransporters as the major mechanism for glucose absorption in the intestine. This was the first significant proposal of a typical coupling between the basic fluxes of a substrate and an ion, and it has been viewed as having efficiently sparked a new revolution in biology. This discovery would not have been possible, however, without the work of Emil Fischer, who had actually discovered the structure and chemical properties of the molecule glucose, for which he was awarded the 1902 Nobel Prize in Chemistry, nearly 60 years before. Because the process of metabolism entails the breakdown of larger molecules into simpler ones (catabolic processes) and the synthesis of larger complex molecules from these simple particles (anabolic processes), the importance of glucose and its involvement in the formation of adenosine triphosphate (ATP) are fundamental to our understanding of metabolism. Glycolysis, also known as the *Embden–Meyerhof–Parnas (EMP) pathway*, named after the three scientists who discovered it, is one of the main pathways by which breakdown of glucose occurs under both aerobic and anaerobic conditions. These three researchers discovered that the glycolysis is actually a strongly determinant process, which is essential for the functional efficiency of the human body.

Understanding this pathway led to the opening of a new field of clinical biochemistry that participates in the study of metabolic disorders. Subsequently, it was also possible to delineate the difference between the glycolytic pathways in the mammalian and microbial systems.

Major Instrumental Advances

Since the mid-20th century, biochemistry has significantly advanced with the rapid development of more and more new techniques such as electron microscopy, chromatography, radioisotopic labeling, protein nuclear magnetic resonance spectroscopy, X-ray diffraction, and studies of molecular dynamics simulations. These extraordinary techniques have enabled the discovery and detailed analysis of many significant cellular functions, such as the citric acid cycle and glycolysis.

Modern biochemistry was revolutionized after the invention of the primary gene amplification technique called the *polymerase chain reaction* (PCR), which was developed by Kary Mullis in the 1980s. This technique basically allows copying a single gene, which is then gradually amplified into millions of copies and has therefore become a cornerstone in the standard protocol for any biochemist who wishes to work with gene expression. PCR is used not only for basic gene expression research but also in aiding research and clinical laboratories in diagnosing leukemia, lymphomas, and other malignant diseases. Without PCR development, many important advances in the field of protein expression study and bacterial study would not have come to fruition. Along with the development of the basic theory and the process of PCR, the invention of the instrument called the *thermal cycler* proved to be critically important, since the use of PCR would not have been possible without it. This is a clear instance of the combined value of the advancement of technology and the painstaking research that resulted in the development of key theoretical concepts in biochemistry and their subsequent application.

Vitamins

In 1912, the Polish biochemist Casimir Funk put forward the arresting theory that scurvy, beriberi, rickets, and perhaps pellagra were actually

caused by the lack or deficiency of some special substances in the diet, which he named *vitamins*. With the typical exception of vitamin B₁₂ and folic acid, by 1940 all of these substances had been mostly identified, purposely isolated, and chemically characterized.

Before the onset of World War II, not only the structures of almost all the vitamins had been discovered but their actual modes of action had also been largely recognized. Vitamin B₁ (thiamine) deficiency was found to cause polyneuritis in the kidney due to the faulty utilization of pyruvate. It was actually the cofactor thiamine pyrophosphate which proved to be extensively needed for the typical processes of natural or biological decarboxylation of molecules like pyruvate and others. During this era, nicotinic acid was found to be an important growth factor. In addition, its presence is required for the effective biosynthesis of nicotinamide coenzymes, which play an important and fundamental role as typical hydrogen carriers, in both aerobic and anaerobic organisms. This latter fact makes it quite possible that nicotinamide adenine dinucleotide (NAD) was among the first substances ever formed in living cells, perhaps millions of years ago when life on earth greatly flourished in an anaerobic atmosphere. Subsequent observations pointed out the efficacy of pyridoxine, or vitamin B₆, as another important cofactor, shown later to play an important role, in the form of its pyrophosphate, in the amino acid transaminations and decarboxylation.

By midcentury, most of the now well-known vitamins had been discovered and their typical modes of action explained. Pantothenic acid was actually found to be an integral part of the coenzyme A molecule. At this time, biotin had been discovered, and its structure had been totally elucidated, then its mode of action in the path of causing major carbon dioxide assimilation in animal cell metabolism was largely clarified by Feodor Lynen and colleagues.

Molecular Genetics

With its roots in biochemistry and closely allied with molecular biology, another discipline of life sciences with vast potential is molecular genetics. A prime target of its investigations is the genetics of enzyme-deficiency diseases and their

basic clinical aspects. Molecular genetics offers tools for anticipating major health risks and for the prevention of diseases. Yet another related field of importance is molecular pharmacology, which aims to alleviate and cure our aches, pains, and diseases.

Neurochemistry

Another important domain, which emerged in the latter half of the 20th century, is a neurochemistry, which studies the chemistry of the nerves and the brain. Here, the cell surfaces play a fundamental role, as do the *synapses*, the gaps between the terminal dendrites of adjacent neurons where electrochemical events occur between communicating cells. At each synapse there is a ceaseless and rapid surge of potassium, sodium, calcium ions as well as some other ions and amino acids, various types of organic substances, and at specific gates or pores; that is, points having special permeability. A neuron can effectively pass an electrochemical signal to another by a chemical messenger through the synapse and a very long, quite sustained, chained effect is accomplished whereby a typical stimulus at a particular sensory organ is finally communicated to the brain and a response by the brain is generated. The vesicles that exist in the synaptic cleft of the neuron possess a high concentration of chemical messengers. This organized phenomenon of typical exocytosis is the foundation of our understanding of perception and of life functions ranging from simple reflexes to conscious awareness and abstract thought.

Conclusion

Biochemistry interfaces with both biology and chemistry and is concerned with the various chemical processes that occur within living cells. Contemporary biochemistry emerged from what in the late 19th and early 20th century was called *physiological chemistry*, which dealt chiefly with extracellular bodily fluids and the processes of digestion. Biochemistry as such is thus largely, though not quite exclusively, a 20th-century discipline. Molecular biology, which came into existence as an offshoot of biochemistry itself, has come to mean a study of the three-dimensional

structure and function of such biologically relevant and important biomolecules as nucleic acids and proteins. Molecular biology is basically as much a typical interface of biology with chemistry as of general biology with physics. In many such respects biochemistry and molecular biology represent the basic realization of the dream of the mechanistic biologists of the early 20th century, who were convinced that the most fundamental biological processes could of course ultimately be well understood in terms of the fundamental laws of both physics and chemistry.

BIOCHEMISTRY, CONTEMPORARY

Biochemistry is a discipline that examines and implements new knowledge of the physical, biological, and chemical processes within organisms, how these constitute interrelated systems, and how their structures determine their physiological functions. The study of biochemistry describes the structures and mechanisms of life in molecular terms and the evolution of complex physiological functions. The chemical nature of simple organic molecules yields a world of its own—one in which 20 standard amino acids assemble to generate essential functions of complex proteins and structures. This examination of contemporary biochemistry aims to discuss the physical and chemical processes involved within organisms and how larger systems ultimately develop. After a presentation of some basic concepts, the entry provides an explanation of the features of cells, followed by a discussion of the role of nucleic acids in living systems. Next, a detailed review of protein structure and functions precedes a discussion of drug development and technology, which identifies the primary targets of drug research. The entry continues with an account of cellular metabolism and disease and concludes with an exploration of the biochemistry of the brain.

Fundamental Concepts

Life consists of three major properties: (1) the ability to transform energy and matter, (2) the ability to grow and reproduce, and (3) the ability to respond to and modify the environment. Traditional undergraduate biochemistry curriculums introduce the chemistry of life sequentially, separating general chemistry from biochemistry by a year's study of organic chemistry. While governed

by the physical and chemical laws of the nonliving universe, the distinction between the subjects lies in differentiating living organisms from nonliving matter. For example, carbon dioxide is an organic molecule and is also a biochemical substrate for the enzyme carbonic anhydrase, which catalyzes the production of bicarbonate and protons. The resulting Bohr effect is a biological phenomenon in which carbon dioxide reduces hemoglobin's affinity for oxygen. Carbonic anhydrase is itself a biomolecule, yet more complex and animated in its function than carbon dioxide.

Biomolecules are a collection of organic molecules, often complex chemical structures, which, in an organized and hierarchical manner, maintain and perpetuate life governed by the many physicochemical principles associated with the movement of energy through matter. Yet, when trying to understand the chemical processes within and between organisms, what is already known often needs refinement. Acquiring new knowledge of how these molecules interact allows biochemists to formulate potentially alternative models on established concepts. Contemporary biochemistry builds upon traditional knowledge to accumulate a new understanding of perceived biological phenomena that often lead to novel approaches in biotechnology.

Additionally, *biomedicine* is the application of biochemical theories toward insightful discoveries in developmental biology, anatomy, and physiology. Contemporary scientists use fundamental core concepts to find key ways to tackle new problems, so as to develop an increasingly comprehensive understanding of human development and disease, with a focus on case studies and clinical application. Concepts that constitute contemporary biochemistry and distinguish them from traditional biochemistry aim to answer many questions about science and life, and how the two together can broaden perspectives about cellular interactions.

The Cell

All cells share similar chemical features. They contain approximately 70 percent water by mass. They have lipid membranes that separate and protect the intracellular components from the external environment. The organelles and other significant

cell components are composed of four major macromolecules: *proteins*, *lipids*, *carbohydrates*, and *nucleic acids*. Simple organic molecules are used as building blocks for the larger complex macromolecules. The origins of the cell are not well understood, yet there is striking consistency in the biochemistry of life from the simplest prokaryote to complex organisms. Norman Pace presented an insightful perspective on biochemical unity in which he reasons that the phylogenetic tree of life, based on small ribosomal ribonucleic acid (RNA) sequences, indicates that the three domains of simple cellular life—archaea, eukaryotes, and bacteria—have a common evolutionary origin, and that inorganic molecules may have been used to support early metabolic processes. The relative ordering of evolutionary events between the earlier form and the three domains is the subject of an ongoing debate among scientists.

Understanding the nature of cells through exploration, discovery, inquiry, and consideration has led to accelerated advancements in stem cell research. Stem cells are a unique type of cell, which can either remain unspecialized or differentiate into specific cell lineages. Discovering the active biochemical agents that guide decisions made by stem cells provides insight into tissue repair and wound healing treatments.

Nucleic Acids

Genomic information of the cell is stored and expressed by nucleic acids. Nucleic acids are long, linear polymers formed from four types of monomers. Each monomer consists of a sugar, phosphate, and nucleobase. The sequence of the bases yields the information content of nucleic acids. Information storage and active use through metabolic processes ensure fidelity. Optimizing information transfer is provided at the level of genetic replication, which must access and evolve the stored information to be faithful to the environment. Deoxyribonucleic acid (DNA) is the biomolecule responsible for storing information, and as a memory molecule it possesses the collective history of all the environmental factors that led to the survival of our species. The importance of genetic information was noticed after polymeric DNA was inferred by Oswald Avery in 1944 to contain genetic information. In 1953, Rosalind

Franklin made further contributions when she collected X-ray diffraction data on purified DNA, which led to the development of a structural model of the DNA helix by James Watson and Francis Crick. From this era, experimental discoveries from studies of bacteria and bacterial viruses provided evidence that DNA alone functions to store and transmit information.

The structural and biochemical knowledge of DNA gained since the 1970s is now being used in the emerging fields of nanotechnology and biotechnology. The 1970s development of recombinant DNA technology sparked a revolutionary shift in the world of science. Contemporary scientists can now modify DNA sequences in their endogenous contexts and observe the functional organization of the genome at a systems level. Continued study of prokaryotic organisms such as bacteria and an increased understanding of their adaptive strategies against viral infection led to the discovery of the clustered regularly interspaced short palindromic repeats (CRISPR) system by Yoshizumi Ishino in 1987. In 2020, Jennifer Doudna and Emmanuelle Charpentier received the Nobel Prize in Chemistry for developing the system into a genome editing tool in which the CRISPR nuclease cas9 is targeted by a short guide RNA that recognizes the target DNA of choice and integrates exogenous DNA into endogenous sites. Precise modification of genetic building blocks could further enhance drug development processes and medical therapeutics by introducing new drug targets or correcting harmful mutations. Knowledge of DNA modification is imperative for understanding, teaching, or experimenting in contemporary biochemistry and impacts research in bacterial genetics, prokaryotic genetics, prokaryotic gene regulation, developmental biology, and cancer.

Another area of interest is messenger RNA (mRNA) vaccines, which were released under emergency authorization in response to the COVID-19 pandemic in 2020. As noted by science writer Elie Dolgin, in the journal *Nature*, the history of mRNA vaccines is not straightforward. Multiple threads of interwoven discoveries from many scientists contributed to the mosaic of knowledge that led to the repurposing and delivery of mRNA as a vaccine. As it stands, a small segment of mRNA corresponding to an

encoded area of the viral protein is introduced into the cell. Once translated into protein, an immune response is generated in which antibodies are produced and can recognize and mark invading viruses for destruction. Lipid-based nanoparticles are an essential strategy for mRNA delivery, since mRNA is unstable and unable to cross the lipid membrane owing to its negatively charged backbone. The lipid nanoparticles enclose the negatively charged RNA strand, which enables mRNA transport across the lipid membrane and evades detection by RNases once inside the cell. Many details of this process are still not well understood and are an area of interest for biochemists.

Protein Structure and Function

The unpacking of encoded information into proficient proteins occurs at the ribosome in a process called *translation*. Proteins are composed of amino acids linked together by a peptide bond. The distinct ordering of amino acids determines the primary structure of proteins. The diversity of proteins arises from the unique primary sequences of amino acids and their side chains. Proteins fold to create three-dimensional structures with multiple levels of organization. Secondary structures are held together by hydrogen bonding within the backbone of a single polypeptide chain, which collapses into a foldable tertiary structure driven into self-organization and stabilization by the hydrophobic effect. Noncovalent interactions such as hydrogen bonding, ionic bonds, and dispersion forces occur between side chains and help to further stabilize the tertiary structure of a single polypeptide chain. Additional stabilization is provided when the side chains of the amino acid cysteine are oxidized to form disulfide bridges, which are covalent bonds and stronger than noncovalent interactions. Quaternary structures arise from the same folding principles of tertiary structures but occur between multiple polypeptide chains.

Protein folding does not appear to be a random process. A protein with four disulfide bonds can fold in a matter of seconds, even though there is a 1/105 probability of reforming the bonds correctly. The bacteria *Escherichia coli* can make a functional protein in 5 seconds, which includes translation and folding, but if each possible conformation was sampled, it would take 10^{77} years to sample a

reduced number of conformations for a protein containing 100 amino acids (single vibration is 10^{-13} seconds per conformation; 10 different conformations per amino acid). In the hierarchical model of protein folding, hydrogen bonding helps to stabilize local areas of secondary structure, which may narrow the number of possible rearrangements, with distant areas folding together through the hydrophobic effect. This differs from the molten globule model in which the polypeptide chain collapses into a compact globular structure driven primarily by the *hydrophobic effect*, whereby a gain in the stability of the folded protein is due to the release of ordered water molecules from nonpolar side chains of the polypeptide. The brief time that it takes to fold shows that all the information necessary for protein folding is present in the primary sequence. Computational biochemistry builds upon this knowledge by providing insightful discoveries into the mechanism of protein folding with computational software that predicts protein structures based on sequence and structure homology.

Proteins exhibit a multifunctional nature. At a physiological level, proteins are the primary drivers of metabolic processes and the expression of phenotypic function. At the cellular level, proteins serve as enzymes, hormones, or antibodies; additionally, there are structural and membrane-bound proteins. The geometric and chemical complementarity between proteins and their substrates or ligands ensures selectivity, and at a grander scale it enriches the structural and functional diversity of cellular proteins. *Enzymes* are proteins that catalyze reactions in the human body. They cannot change the direction of the reaction but can lower the activation energy needed to speed up a reaction—in other words, how fast the reaction reaches equilibrium. While most enzymes are proteins, in some cases, RNAs are also capable of catalyzing reactions. As biochemical catalysts, enzymes are often regulated by effector molecules and inhibitors. They are often dependent on cofactors that assist in functional group transformations and redox reactions.

Drug Development and Technology

Academics, clinical researchers, and the private sector continue to collaborate in developing specific compounds against targets. G-protein receptors

(GPCRs), the ribosome, and enzymes are known to be amenable targets for drug discovery. The *ribosome* is the site of protein synthesis, translating genetic information into a linear polymer through the condensation of amino acids. Ribosome inhibitors are among the most successful antimicrobial drugs to treat infections and are a central focus in the development of drug design and mechanisms of inhibition.

Nearly all therapeutic drugs are enzyme inhibitors that perform target-specific functions, and so they continue to play a great role in developing commercial antibiotics and instrumentations. The technological discovery of biosensors, motivated by the need to measure blood glucose levels for patients with diabetes, revolutionized gaining control and analysis of specific conditions. The pioneering efforts of researchers in mutating and inhibiting enzymes have been a significant focus in contemporary science, as they allow for a genome-wide study of enzyme evolution. Through genome sequencing, a recent class of enzymes called *pseudoenzymes* were identified. Pseudoenzymes are proteins that have lost enzyme activity owing to mutations and are now areas of target or anti-target in drug development.

Antibodies are also areas of drug target and development. Monoclonal antibodies—molecules produced in vitro that serve as substitute antibodies—are currently used to fight against infection, since the immune system protects against foreign substances by producing antibodies. Antibodies are specific proteins that target certain antigens and mark them for destruction. They bind to their target cells and kick-start a cascade system to eliminate specified foreign substances. Monoclonal antibodies have high specificity for an antigen or epitope. To effectively design target drugs, scientists are searching to identify mRNA/protein levels to determine gene expression abnormalities and whether the presence of specific proteins correlates with disease progression.

Imitating the body's natural mechanisms for evading foreign pathogens has challenges. In the pathogenesis of a disease, several complex pathways are often involved and driven by proteins. Promiscuous proteins, so called, can sometimes bind to many ligands within living cells, becoming problematic in immunotherapy.

Cellular Metabolism and Disease

Proteins and enzymes affect systems at various levels—from genomic sequences to physiological states of an organism or cell. The dynamic nature of cellular metabolism and disease is a growing concern among contemporary scientists. *Metabolism* is broadly defined as a series of reactions within cells that produce or consume energy for vital processes. It can be subdivided into three classes: anabolism, catabolism, and waste disposal. Traditional biochemists have identified core metabolic networks within these classes as responsible for nutrient utilization and energy production in humans and organisms. These include fundamental processes such as glycolysis, respiration, tricarboxylic acid (TCA) and urea cycles (Krebs), and oxidative phosphorylation. These fundamental processes take food such as carbohydrates or fats and oxidize them into carbon dioxide and water. Energy is extracted and converted into adenosine triphosphate (ATP), the universal currency in biological systems, which pays the price for biological functions such as motion, active transport of molecules across the cell membrane, biosynthesis, and signal amplification.

Research in metabolism is beginning to shift the focus on cellular metabolism toward examining metabolic processes that accompany human diseases. For example, Facundo Fernández and colleagues showed that metabolomic profiling of serous ovarian cancer in mouse models allowed visualization of tissue heterogeneity and lipid alterations in tumor cells, thus providing a tool for understanding disease origin and progression. The regulatory state of a cell or tissue is necessary to realize, as it is often driven by signaling pathways and specific transcription factors, which can impose themselves upon the dynamics of its metabolic state. Contemporary scientists also ask whether the reciprocal idea can also be possible: whether the metabolic state imposes itself on the regulatory state of the cell. Understanding the relationship between cellular-level interactions and biological systems will help discover key proteins and how they function.

Biochemistry of the Brain

The brain is the most complex organ in the human body, composed of an intricate web of synaptic

connections and neurochemicals necessary for a normal functioning central nervous system. The brain accounts for more than 20% of total oxygen metabolism and represents the largest source of energy consumption in a human. Oxidative DNA damage is considered a significant cause of neurological diseases in humans. Mitochondria, a type of organelle within cells, produce reactive oxygen species (ROS) as a by-product of normal cell activity. Michelle Watts and associates have shown that overproduction of ROS and disruption of mitochondria function are consistent causes of many neurodegenerative diseases, such as dementia. The regulation of tissue metabolite supply and cellular energy metabolism is essential to maintaining healthy cellular and systemic function, although prognostic and diagnostic approaches need refinement. Daniel Silverman and colleagues acknowledge that assessing correlations between brain metabolism with neurodegenerative diseases is difficult, since there are only a few cases in which patients are monitored over long-term clinical follow-up. Prolonged studies on the effects of brain metabolism on inner-neuronal connections among a larger patient pool will give rise to answering fundamental questions about cognitive health. Such studies eventually may provide insights into the relationship between memory and biological information, revealing how the retention and active use of information passing through the nervous system and mental processes impacts the way life is experienced and defined.

Systems neuroscience aims to understand how complex interactions between networks of neurons give rise to perception, behavior, and neurodegenerative diseases. The catecholamine neurotransmitter dopamine (DA) plays an essential role in behavioral and cognitive functions relating to memory, motivation, learning, and movement. The progressive degeneration of neurons of the substantia nigra causes a depletion of DA in areas of the brain and can lead to disorders such as Parkinson's disease. Richard Meade and associates report that the etiology of Parkinson's disease remains unknown, but the pathogenic hallmark of the disease is associated with protein misfolding and the presence of alpha-synuclein, which is itself poorly defined both in structure and function. According to Marek Cieřlak and colleagues, dopaminergic agonists, in conjunction

with the dopamine precursor L-DOPA, are used to slow the dopaminergic neurons' progressive death. The complex nature of the brain's chemistry and structure continues to perplex scientists, as poor diagnostic tools and the lack of reliable biomarkers complicate the selection of drug targets and candidate molecules. In addition to stem cell treatments, contemporary biochemists are working to produce efficient drug targets that surpass the blood-brain barrier, a highly selective border of endothelial cells.

Many avenues have been explored with drugs on the study of the brain and the biochemical basis for protein misfolding in neurodegenerative diseases. Yet, there remains a vast landscape of unknowns for contemporary biochemists to explore, particularly in how to unify neurochemical processes with recent machine technologies. Furthermore, abstract notions of human existence and reality are fundamentally created by neurochemical processes, yet the reconciliation of these two concepts is far from complete. Their fundamental claims ask the same questions scientists have asked for centuries: How is the external knowledge of the world possible in science? Questions concerning the meaning of life must be accounted for at a molecular level as well as at the universal level. Although yet to be convincing, Freeman Dyson once offered an explanation to reconcile the higher centers of human consciousness and the lower level of atoms: namely, that consciousness is not just a byproduct of neurochemistry but an active agent, forcing atoms and subatomic particles to make choices between one quantum state and another.

The more options, or choices, the higher the probability. This is one way to interpret entropy. Macroscopic properties emerge from microscopic interactions, which are often driven to rearrange molecules in space by entropy. Choice continues to be an interesting theme to consider, whether it concerns the mind, the differentiation of stem cells, or the quantum states of particles. Contemporary scientists have yet to develop a way to explore the notion of intellectual intuition in human life with neurochemical processes. The reality of things in how they are perceived and how this is coextensive with the mind thinking those things may help scientists to understand whether or how intuition is a form of cognition,

and how organisms can receive sensory data and form understanding. Emerging subgenres of contemporary biochemistry—drug-target kinetics, neuroscience, brain–machine interfaces, metabolic disorders, and nutrition—dive into such ideas surrounding the human condition.

BIOINFORMATICS

Paulien Hogeweg and Ben Hesper coined the term *bioinformatics* in 1978 to refer to the study of informatics processes in biotic systems. Bioinformatics is the application of information technology to the field of molecular biology and more generally asking biological questions with a computer. There was a time when biology happened mostly in dissection labs and test tubes and under microscopes. Owing to the development of genomic technologies, biology has been transformed from a science in which the human effort was mainly oriented toward data gathering to a science that generates a huge volume of data. Many scientists today refer to the next wave in bioinformatics as systems biology, a new approach to tackling new and complex biological questions. The range of possible applications of bioinformatics is enormous: molecular biology, clinical medicine, pharmacology, biotechnology, forensic science, anthropology, and many other disciplines.

Use of Sophisticated Analytic Tools

Bioinformatics is about searching biological databases, comparing sequences, and looking at protein structures. Systems biology involves the integration of genomics, proteomics, and bioinformatics information to create a whole-system view of a biological entity.

The origins of bioinformatics derive from the existence of biological databases. The first bioinformatics or biological databases were constructed a few years after the first protein sequences of amino acids became available, resulting from work on insulin in 1956. After the formation of the databases, tools became available to search sequence databases. Since these early efforts, significant advances have been made in automating the collection of sequence information. Rapid innovation in biochemistry and instrumentation has brought us to the point where the entire genomic sequence of several organisms is known. Projects to elucidate more than 100 prokaryotic and eukaryotic genomes are currently under way. The Internet is the virtual laboratory in which genomic research is now conducted.

In the early 1990s, scientists at the European Organization for Nuclear Energy (CERN) invented the World Wide Web (WWW) technology on the Internet (the now ubiquitous computer network developed earlier in the United States). The Web was the platform that solved many problems of maintenance, update, access, and integration of databases in molecular biology. In a way, without the WWW technology, the Human Genome Project would not have been possible.

The information archive within each organism is its genetic material (DNA and RNA). The human genome is only one of the many complete genome sequences known. The ENCODE Project (ENCyclopedia Of DNA Elements) has the ultimate goal of developing methods for comprehensive identification of functional regions of the human genome, including coding and regulatory regions.

Roderic Guigó, one of the main characters in the race for the genome project culmination, said that life begins when the nucleotides are arranged in the sequence of the genome. It is the particular order of nucleotides in this sequence, rather than its physical and chemical properties, that dictate the biological characteristics of living beings.

The human genome sequence is now complete, and it is joined with 18 archaea, 155 bacteria, and over 30 Eukarya, as well as many other organelle and viral sequences that are now known.

Key databases containing this information include the archive of nucleic acid sequences known as the International Nucleotide Sequence Database Collection, maintained by GenBank, based at the U.S. National Center for Biotechnology Information, in Bethesda, MD; the EMBL Nucleotide Sequence Database, or EMBL-Bank, based at the European Bioinformatics Institute, in Hinxton, U.K.; and the Center for Information Biology and DNA Databank of Japan, located at the National Institute of Genetics in Mishima, Japan.

The archive of amino acid sequences of proteins is maintained by The United Protein Database, a merger of the databases SWISS-PROT, The Protein Identification Resource, and Translated EMBL. Three systems use Web technology to facilitate access to genomic information via distributed databases: ENSEMBL in Europe and NCBI and Genome Browser, both in the United States.

The implementation of genetic information occurs through the synthesis of RNA and proteins.

However, not all DNA is expressed in proteins or structural RNA. Most genes contain internal untranslated regions called *introns*. Some regions of the DNA sequence are devoted to control mechanisms, and for a substantial number of regions, we do not yet understand the function. Proteins, in contrast, show a great variety of three-dimensional configurations with diverse structural and functional roles. Originally, bioinformatics concentrated on the study of the genome, but today it also extends to the study of the proteome, involving the patterns of gene expression and the complex networks of regulatory interactions associated with protein functions.

Alignment: Toward Structure and Function

Aligned sequences of nucleotide or amino acid residues are typically represented as rows within a matrix. In the precomputer era, sequences of DNA, RNA nucleotides, or protein amino acids were assembled, analyzed, and compared manually. Later, these problems were solved using algorithms instead. An algorithm is a complete and precise specification of a method for solving a problem. As soon as computers became available, the computational biologist started to enter these manual algorithms into the machines.

In general, this new discipline called *bioinformatics* could be summarized in the term *alignment*. In bioinformatics, a sequence alignment is a way of arranging the sequences of DNA, RNA nucleotides, or protein amino acids to identify regions of similarity that may be a consequence of functional, structural, or evolutionary relationships among the sequences. Sequence—structure—function: This is now a central concept of both molecular biology and bioinformatics.

Protein sequence alignment has become an essential task in modern molecular biology research. A number of alignment techniques have been documented in the literature, and their corresponding tools are made available as both free-ware and commercial software. The two most commonly used programs are the Basic Local Alignment Search Tool (BLAST) and FASTA. BLAST finds regions of local similarity between sequences. The program compares nucleotide or protein sequences to sequence databases and calculates the statistical significance of matches.

BLAST can be used to infer functional and evolutionary relationships between sequences and to help identify members of gene families. BLAST was developed to provide a faster alternative to the earlier FASTA without sacrificing much accuracy.

These programs are an ideal starting point to determine whether a related sequence, or a family of sequences, already exists in a database. The results from these programs will provide evidence of function, utility, and completeness of the gene product. In the 21st century, the sensitivity of sequence searching techniques has been improved by profile-based or motif-based analysis, which uses information derived from multiple sequence alignments to construct and search for sequence patterns.

BIOLOGY, EVOLUTIONARY

Evolution is the study of the history of life on earth and how it has changed over time. One of the most famous statements on the subject is Theodosius Dobzhansky's 1973 dictum, "Nothing in biology makes sense except in the light of evolution" (*The American Biology Teacher*, p. 125). As we shall see, it is equally true to note that nothing in evolution makes sense except in the light of biology. Over almost three centuries of modern thought on the topic, theories of evolution have been shaped by the current status of knowledge about biological processes, most especially the nature of heredity and hereditary variation. The major key to

understanding why evolution theories have changed and continue to do so today is to be found in new technical and conceptual advances in the science of inheritance. We are in a revolutionary period in study of that subject because we can now directly read and modify genomic DNA sequences. Consequently, the topic of evolution currently has more complexity and intellectual ferment than the general public realizes.

Setting the Scientific Stage for Evolutionary Thinking

Although in antiquity there were some precursors to ideas about evolution, the dominance of religious thought about divine creation of all living organisms dominated the Christian and Islamic worlds through the Middle Ages and even survives today among fundamentalist groups of both faiths. The scientific basis for modern ideas about evolution originated in the 18th and early 19th centuries around two related subjects: taxonomy and paleontology.

Although he believed in the fixity of species, the main figure in the origins of scientific classification and the idea of biological relatedness was the Swedish scholar Carl Linnaeus (1707–1778). In 1751, Linnaeus published *Philosophia Botanica*, setting out the bases for taxonomic classification into species and classes of species by defining relationships through particular inherited characteristics plants did or did not share.

The systematic study of fossils and their connection to taxonomy originated with the Frenchman Georges Cuvier (1769–1832). Known as the founding father of paleontology, Cuvier studied vertebrate paleontology in the context of comparative anatomy. He extended Linnaean taxonomy by recognizing that multiple classes could be grouped into higher level classifications called *phyla* and by incorporating both fossils and living species into the classification scheme. The inclusion of fossils of no longer living organisms established the complementary realities of species extinction and survival by distinct but recognizably similar species. While the extinction/survival duality has become critical to evolutionary thought, Cuvier too accepted the fixity of species. He was the first scientific catastrophist and interpreted the fossil record as evidence for recurring

cycles of species destructions in global mass extinction events followed by creation of functionally similar species without an intermediate process of biological transformation.

Descent With Modification, Natural Selection, and the Origin of Species

The transition to thinking about the diversification of life as a biological process of acquiring and modifying inherited characteristics, known as Descent with Modification, had its origins in the late 18th and early 19th centuries. The idea that living organisms could undergo hereditary variation and transform themselves to new life forms arose in Britain and France. In Britain, the major figure was Erasmus Darwin (1731–1802), Charles's grandfather. He had translated Linnaeus from Latin into English with two colleagues. In E. Darwin's most important scientific work, *Zoonomia* from 1794, he anticipated the modern theory of evolution:

Would it be too bold to imagine, that in the great length of time, since the earth began to exist, perhaps millions of ages before the commencement of the history of mankind, would it be too bold to imagine, that all warm-blooded animals have arisen from one living filament, which THE GREAT FIRST CAUSE endued with animality, with the power of acquiring new parts, attended with new propensities, directed by irritations, sensations, volitions, and associations; and thus possessing the faculty of continuing to improve by its own inherent activity, and of delivering down those improvements by generation to its posterity, world without end! (p. 453)

Erasmus Darwin also anticipated survival of the fittest in *Zoonomia* mainly when writing about the “three great objects of desire” for every organism: “lust, hunger, and security...the strongest and most active animal should propagate the species, which should thence become improved” (p. 452).

In France, the first comprehensive statement of evolution by “transmutation of species” came from the French self-described student of “biology,” Jean-Baptiste Lamarck (1744–1829), in his 1809 *Philosophie Zoologique*. Lamarck was the first scientist to state explicitly that all species arise

from other species and illustrate a branching “tree of life” for animals (p. 649). Lamarck's solution to explaining the apparent direction of evolution was to postulate an inherent drive toward greater organismal complexity (“le pouvoir de la vie,” the life force) and environmental inputs by change linked to the use and disuse of characters that distinguish one species from another. The life force postulates an inherent goal-oriented drive or teleology to the evolutionary process, different from Erasmus Darwin's “lust, hunger, and security,” and has been denounced by modern evolutionary biologists as unscientific. The second adaptive factor is the well-known “inheritance of acquired characteristics.” That process has been singled out by Darwinists to distinguish Lamarck from Charles Darwin as an evolutionary theorist, although Darwin himself explicitly subscribed to the same idea in *Origin of Species* (chapters 5, 6, etc.).

The turn to what is considered by most people to be the definitive theory of evolution came in 1858 with the publication of papers by Alfred R. Wallace and Charles Darwin entitled jointly “On the Tendency of Species to Form Varieties; and on the Perpetuation of Varieties and Species by Natural Means of Selection” (Vol. 3 of *Zoological Journal of the Linnean Society*). The major advances proposed by Darwin and Wallace were (a) discarding any appeals to unexplained internal forces or drives, (b) the assumption of random variation in inherited organismal properties, and (c) the concept of evolutionary advances resulting from differential reproductive success of organisms with improved adaptive characters in a Malthusian struggle for survival and reproduction. In the Darwin–Wallace theory, the purely objective process of *natural selection* for reproductive advantage determined the course of evolutionary change. Darwin explained this idea in the subtitle to his 1859 book, *On the Origin of Species by Means of Natural Selection, or the Preservation of Favoured Races in the Struggle for Life*.

Since its introduction, evolution “by Means of Natural Selection” has received broad acceptance as a foundational explanation of the evolutionary process. However, there were basic missing elements in Darwinism, as even Wallace came to call it (A. R. Wallace, 1889, *Darwinism*). Understanding “Descent with Modification” requires a theory of hereditary transmission and of how hereditary

variants altering adaptive traits arise. Darwin and Wallace had neither, because the fundamental biology was missing. Moreover, Darwin made some *ad hoc* assumptions about variation, apparently influenced by the uniformitarian views of his Edinburgh geology professor, Charles Lyell (1767–1849). Darwin quoted Linnaeus's statement "*Natura non facit saltus*" (Nature does not make jumps) and insisted on evolutionary advances by gradual change over long periods of time in his first edition: "If it could be demonstrated that any complex organ existed, which could not possibly have been formed by numerous, successive, slight modifications, my theory would absolutely break down. But I can find out no such case" (*Origin of Species*, 1859, chap. 6, p. 189). Only later, in his 1872 6th edition, did Darwin recognize "sports" as discontinuous "variations which seem to us in our ignorance to arise spontaneously. It appears that I formerly underrated the frequency and value of these latter forms of variation, as leading to permanent modifications of structure independently of natural selection" (chap. 15, p. 395). As we shall see later, the issue of punctuated versus continuous change has come to be one of the key issues in debates over evolution theory for the last 80 years.

The Science of Heredity: Mendelian Genetics, the Modern Synthesis and the Central Dogma of Molecular Biology

While Darwin and Wallace were proclaiming the idea of evolution by natural selection, the unknown Czech monk Gregor Mendel (1822–1884) took the first steps toward filling in our knowledge about the biological basis of heredity. Mendel documented the regular inheritance patterns of discrete dominant and recessive factors determining coat color and seed shape in breeding (hybridization) experiments with peas in 1866. His results contradicted the prevailing idea that somehow the properties of the parents were blended in their offspring. Mendel must have appreciated the relevance of his findings to evolution because he sent his paper to Darwin, but Darwin ignored it, as did the rest of the scientific world for over 30 years. In 1900, at least two botanists searching for discontinuous inheritance, Hugo de Vries and Carl Correns, rediscovered Mendel's paper and confirmed his rules governing specific trait inheritance.

The widespread dissemination of Mendel's rules at the very start of the 20th century led to an explosion of research and the development of the science of Mendelian genetics, which initiated the scientific examination of biological heredity. The Danish botanist Wilhelm Johannsen (1857–1927) introduced the term *gen* (gene) in 1903 to denote any kind of inherited factor that follows Mendel's rules and in 1909 coined the terms *genotype* (an individual's complete collection of inherited factors) and *phenotype* (the individual's visible properties influenced by the inherited genes). Genetic and microscopic analysis of model organisms, such as maize (corn) and the fruit fly *Drosophila melanogaster*, studied by Thomas Hunt Morgan and his colleagues, established the chromosomes in the eukaryotic cell nucleus as the physical structures carrying Johannsen's genes from one generation to the next. Microscopic and genetic analysis dissected the chromosomal basis for sexual reproduction by haploid gamete (sperm/pollen, egg/ovule) formation in meiotic cell divisions. These studies defined homologous chromosome pairing as a critical step in meiosis that has two major evolutionary consequences:

1. Meiotic chromosome pairing facilitated recombinational exchanges between homologues to generate novel combinations of gene variants along each chromosome and thereby produced additional hereditary variation. This process was quickly recognized and incorporated into mainstream evolution theory.
2. Pairing also restricted successful mating to organisms which shared the same chromosome and thus contributed to reproductive separation of closely related species that had different "karyotypes" or structural nuclear constitutions. Mainstream evolutionists resisted highlighting this feature of species differentiation.

In the 1920s to 1930s, the mathematically gifted pioneers J. B. S. Haldane, Ronald A. Fisher, and Sewall Wright developed the quantitative discipline of population genetics, which adapted the discontinuous, gene-based approach of Mendelian genetics to the idea of continuous evolutionary change. This new, highly statistical approach treated the distribution of the ensemble of individual gene variants within populations as a

major source of evolutionary variation: Natural selection of individuals with favorable combinations of alleles would change the “gene pool” and provide significant adaptive advantages. The assertion that “evolution is a change in gene frequencies” was made on more than one occasion. Together with geneticists, naturalists, and less quantitative theorists, the population geneticists promulgated the modern synthesis (ModSyn) of Darwinism and Mendelian genetics in the early 1940s as a comprehensive and, they believed, definitive scientific statement of evolutionary change. This quickly became the mainstream view of evolutionary processes in the 1940s and has remained so in the public awareness over the past 80 years.

The ModSyn retained Darwin’s view of random mutations making small differences in phenotypic traits that could be selected over time to produce major adaptive novelties. To these random mutations, the ModSyn added genotypic and phenotypic variability resulting from meiotic recombination, patterns of chromosome transmission, and population-level events. Exceptional occurrences of major genotypic change associated with formation of new species or taxonomic groups were explicitly excluded. In the words of Ernst Mayr, a major figure in the ModSyn: “The proponents of the synthetic theory maintain that all evolution is due to the accumulation of small genetic changes, guided by natural selection, and that transspecific evolution is nothing but an extrapolation and magnification of the events that take place within populations and species” (1970, p. 351).

The early years of biochemical genetics and molecular biology appeared to reinforce the ModSyn. One major unanswered question was, how does genetic information function to specify phenotypic characters? The answer came in 1941 from genetic experiments with the fungus *Neurospora crassa* when George Beadle and Edward Tatum reported that mutants deficient in biosynthetic capacity lacked specific enzymes. Their “one gene–one enzyme” hypothesis was rapidly generalized to “one gene–one protein,” and the information content of the genotype was interpreted to consist of the instructions for the synthesis of an organism’s complete repertoire of proteins, the molecules with the biochemical abilities needed to construct a phenotype.

The 1944 discovery by Oswald Avery and colleagues that DNA carries genetic information in bacteria and by Alfred Hershey and Martha Chase in 1952 that bacterial viruses inject DNA into their hosts when they reproduce quickly led to working out the DNA double helix structure in 1953 by Rosalind Franklin and Ray Gosling, James Watson, and Francis Crick. The structure of DNA immediately answered two questions about this central molecule of heredity: How it is able to duplicate accurately, as required for genotype maintenance during cell division and growth? and How it could specify the sequence of amino acids in protein molecules by a nucleotide sequence code? Working out the details of protein synthesis and the genetic code for amino acids in the products inspired Crick to articulate the “central dogma” of molecular biology, which states that sequence information flows unidirectionally from DNA to RNA to proteins, sometimes from RNA to DNA, but never from proteins to DNA. This tidy division of labor in cellular informatics also fit very well with the ModSyn view of the genotype as the controlling blueprint for organismal characteristics. It also provided a molecular explanation of random genetic change as DNA replication errors.

Diverging Views Prior to the Modern Synthesis

The most arbitrary feature of the ModSyn—and of Darwin’s original theory in *Origin of Species*—was the *ad hoc* assumption that the mutational events generating hereditary variation in the first place must be random accidents of small phenotypic consequence. There was no evidence that this was actually correct. The gradualist assumption was made to give predominance to natural selection as a directing force and it effectively assigned a purely passive role to the organism in the evolutionary process. In discussions of evolutionary change over time, there had always been an ongoing debate between gradualists like Darwin and saltationists, such as Hugo de Vries, who believed that nature does make discrete mutational leaps, which can explain the origins of many diverse life forms. A very different disagreement with evolutionary gradualism came from Russian and American scientists who studied cell biology and

proposed that cell fusions between distinct organisms had generated completely novel hybrids by an abrupt process called *symbiogenesis*, whereby one cell becomes an internalized organelle of the new hybrid. This argument was revived in the 1970s by Lynn Margulis (1938–2011) to explain the origins of eukaryotic cells. Both saltatory and symbiogenetic views were treated as far-fetched fantasies by ModSyn followers.

The most serious contemporaneous intellectual challenge to the ModSyn was posed by the developmental geneticist Richard Goldschmidt in his 1940 book, *The Material Basis of Evolution*. Goldschmidt argued that a fundamental difference exists between the accumulation of localized mutations in particular genes that account for *microevolution* improvements that remain within each species and the occurrence of structural changes to the chromosomes that produce *macroevolution* changes forming new species. Goldschmidt also argued that mutational alterations in embryonic development could produce “hopeful monsters,” organisms with major morphogenetic changes (i.e., “monsters”) that occasionally would provide adaptive benefits (i.e., “hopeful”), as a way to explain major changes in organismal body plans. The mainstream ModSyn evolutionist community dealt with Goldschmidt’s well-documented dissent by a form of scientific excommunication, either totally ignoring him or relegating his views on evolution to what they saw as the clearly preposterous hypothesis of “hopeful monsters.” (Today, of course, the hopeful monster idea is seen as the beginning of a major field studying the evolution of multicellular development, widely known as *evo-devo*.)

Problems Arising After the Modern Synthesis

One major problem came out of the research of a plant geneticist credited with being one of the ModSyn founders, G. Ledyard Stebbins. Stebbins studied the role of hybridization between different plant species to generate new organisms for agriculture. He documented the rapid formation of new plant species with new chromosome constitutions following interspecific hybridization and called this process *cataclysmic evolution* (*Scientific American*, April 1951, p. 54). While

Stebbins himself considered his observations a special exception to gradual speciation, they exposed a major evidentiary problem for ModSyn arguments. No amount of gradual selection for changes in individual traits ever produced a novel species, but a very different process has been generating them in agriculture for thousands of years (at least since the origins of flour wheat in the Fertile Crescent about 10,000 years ago in Stebbins’s 1951 narrative).

The most transformational results challenging the assumptions of the ModSyn came from two markedly different sources in the middle of the 20th century. The first source was Barbara McClintock’s studies of chromosome breakage and repair in maize. McClintock found in the 1930s that what were thought to be X-ray-induced “gene mutations” were actually the products of chromosome breakage repaired by the maize plants. She then set out to study chromosome breakage and repair. She documented processes of major chromosome restructuring and unexpectedly discovered genetically mobile “controlling elements” that could insert at new genome locations, where they reprogrammed patterns of expression by adjacent genes. McClintock’s results received a hostile reception when she first presented them to a scientific meeting in 1952, but she was ultimately vindicated and received a Nobel Prize in 1983, recognizing that her controlling elements are universal in biology.

The second transformational episode was humanity’s worldwide evolution experiment combating bacterial pathogens with antibiotics after World War II. When the ModSyn was formulated, it was still debated whether prokaryotic cells without a nucleus had any genetics at all. But postwar experiments pioneered by medical microbiologists and physicists-turned-molecular-biologists established the science of bacterial genetics. However, the rules were strikingly different from those of eukaryotic Mendelian genetics. Bacteria had so-called *infectious heredity* and could readily transfer DNA from cell to cell, often between unrelated types of cells. When antibiotic resistance emerged as a serious clinical problem in the 1950s and 1960s, it did not originate by localized mutations as had been predicted—and experimentally confirmed in laboratory experiments. The resistance determinants

were carried by transmissible DNA molecules, and these “R-factors” accumulated resistances to multiple antibiotics by acquiring mobile DNA elements analogous to those discovered by McClintock. Bacterial versatility in engineering and spreading novel DNA structures is one of the reasons that multidrug-resistant “superbugs” now threaten our health.

Bacterial genetics was also central to pioneering studies of how cells control genome expression. Such studies began to dissect the “gene” and identified two features of genomes absent from the ModSyn: (1) the presence of regulatory DNA sequence elements needed to control the expression of every genetic locus and (2) the shared use of repeated regulatory elements at multiple loci to establish control networks across the genome. In bacteria, but even more so in complex eukaryotes, these multi-locus networks regulate the expression of protein-coding genes under changing conditions. They are the reason so many phenotypes have complex multifactorial genetic determination. Explaining how multisite networks evolved is a serious challenge for ModSyn gradualism but is a straightforward application of the genome-wide distribution of mobile controlling elements.

What Does Genomics Tell Us?

Now that we are able to read DNA and RNA sequences, we need to formulate a more genomics-based view of evolution. One of the first results of sequencing was the discovery by Carl Woese and colleagues as recently as 1977 that bacteria are not the only prokaryotic organisms on earth. There is an equally ancient, abundant and diverse, but evolutionarily distinct kingdom named *Archaea*. This unexpected discovery ultimately led to molecular confirmation of the symbiogenetic origin about 1.8 billion years ago of the ancestor of all eukaryotes by fusion of a *Proteobacterium* ancestor to the mitochondrion and an *Asgard* archaeon related to the eukaryotic cytoplasm. The eukaryotic nucleus contains sequences of both bacterial and archaeal origin, but how it formed as a separate organ of the cell remains unknown. Genome sequencing has also confirmed the symbiogenetic origins of algae, plants, and other photosynthetic eukaryotes. Thus, the deepest evolutionary divisions in biology that

we can explain arose symbiogenetically, not by Darwinian gradualism.

Other features of eukaryotic genome evolution require the formulation of novel theoretical perspectives. The first of these is the discovery of *horizontal DNA transfer* across all phylogenetic boundaries. Examples include bacterial and fungal DNA sequences encoding digestive enzymes in herbivorous invertebrates and sequences encoding eukaryotic regulatory proteins in bacterial pathogens, where they serve to establish the bacterium as an intracellular parasite. Acquiring horizontally transferred proteins that execute specialized functions means that the evolution of key adaptive traits need not be a slow gradual process. The patterns of horizontal transfers are numerous and complex and indicate multiple modes of DNA acquisition. For some researchers in this area, the Tree of Life has transformed into a branching Web of Life.

One of the most important features of complex eukaryotic genomes, the presence of large amounts of repeated DNA sequences, was discovered pre-sequencing in 1968 by a simple biophysical experiment. The presence of abundant DNA repeats in the genome did not accord with the idea of chromosomes carrying unique protein-coding genes like “beads on a string” and demanded an explanation. The response was to call this repetitive DNA “junk,” which accumulated because it had “selfish” properties of replicating faster than unique coding DNA in the genes. Richard Dawkins even elaborated a whole philosophy on the basis of *The Selfish Gene* (1976). Such ideas notwithstanding, sequencing the human and other genomes plus functional studies have revealed important adaptive features of repetitive DNA elements (which outnumber protein-coding sequences in our genome by a factor greater than 30:1):

1. The majority constituents of repetitive DNA are mobile genetic elements distributed throughout the genome.
2. Many of these dispersed mobile elements have been co-opted in evolution as regulatory sites for proper expression of coordinated genome networks encoding complex traits such as pregnancy in mammals.

3. Other dispersed mobile elements serve as part of the DNA templates for the formation of noncoding “ncRNAs,” which encode no proteins but instead fulfill a rapidly growing list of cell regulatory functions, some of which depend upon the repetitive nature of the sequences they contain.
4. A minor fraction of repetitive DNAs consists of tandem repeat arrays that format the chromosomes for proper replication and distribution at cell division. Some arrays also play roles in formatting the genome for epigenetic control of chromatin structure.

In summary, the repetitive DNA story tells us that genomes do more than encode proteins and that we will always find unexpected features, like regulatory ncRNAs, as we delve deeper into the biological basis for evolution. Repetitive DNA elements are typically the most labile genome components in evolution because the majority of the protein-coding sequences are essential for shared functions and conserved by selection, but the regulatory framework involving DNA repeats can change more freely as species diverge.

Mobile DNA elements have been the subject of comprehensive genetic and biochemical analysis. Although these elements come in many forms (e.g., viruses that integrate into cell genomes, *transposons* that migrate within genomes through DNA intermediates, *retrotransposons* that migrate through RNA intermediates), the proteins and nucleic acids involved in genetic mobility have been thoroughly characterized. In particular, the proteins that execute mobile DNA movements in the genome are nonrandom in their actions on the mobile element itself, and many have been found to be targetable for new insertions to particular sites or classes of sites in the genome. Additionally, various ecological triggers and stresses can activate the mobilization of these DNA elements. Thus, for a significant portion of evolutionary mutability, the changes are nonrandom with respect to both genome location and life history events.

While mobile DNA elements sometimes cause large-scale genome rearrangements, it has unexpectedly been the study of somatic evolution in cancer that has significantly expanded our

understanding of major genome restructuring under stress in the 21st century. Whole genome sequencing of various tumor cells revealed highly nonrandom patterns of multiple DNA rearrangements that had occurred in a single chromosome or in a small subset of the 24 human chromosomes. We know from direct observation that these rearrangements often occurred in a single cell division. The concerted rearrangements are triggered by cell division errors and have received colorful names, such as *chromothripsis* (“chromosome shattering”) and *chromoplexy* (“chromosome weaving”). Although cancer might be considered an aberrant condition and irrelevant to organismal evolution, the same nonrandom multisite rearrangement patterns were quickly found to occur in the human germ line and in other animals and in plants. The detailed biology of chromothripsis involves the ability of eukaryotic cells to encase “lagging” chromosomes or fragments left off the mitotic spindle in special subnuclear compartments and to recruit hyper-mutagenic DNA repair enzymes to catalyze the complex multisite rearrangements and generate a level of genome variability that would have been totally inconceivable at the time of the ModSyn.

The Beginnings of a Genomics-Based Theory of Evolution

The study of phenomena like noncoding DNA and ncRNA regulation, the evolutionary utilization of mobile DNA elements to form genomic regulatory networks, and the potential for rapid multisite genome restructuring combine to provide a dramatically different picture of what a genome is and how it can change in evolution. Rather than merely a string of protein-coding genes, the genome has become an intricately formatted and structured database encoding proteins and RNAs, which feed back onto the genome to ensure the correct expression of specific organismal characters. Rather than possessing a read-only ROM memory system that changes gradually by random copying errors, we know that evolving organisms have the biochemical and cellular tools to rapidly restructure their read-write genome databases in macroevolutionary transformations into new species with novel

adaptive traits. Unlike the ModSyn and the central dogma, the genomics-based theory envisions the organism playing an active role in changing its DNA in a manner responsive to its life history and ecology. This means that punctuated equilibrium should be the default mode of macroevolution. The main questions for the future will probably have less to do with biochemical details than with cybernetic questions about how complex DNA changes successfully produce adaptively useful biological novelties.

BIOPHYSICS, 19TH CENTURY

While the discoveries of inorganic chemistry were quickly advancing during the end of the Enlightenment period and the Chemical Revolution, many new avenues of scientific inquiry were being born. In the areas of physics and chemistry in particular, new methodologies such as mechanics (engineering and optics) and chemical production (chemical factories) were quickly laying the foundations for invention and chemical knowledge. In fact, the drive to develop industries contributed to the feverish pursuit of scientific knowledge that could be applied in the industrial arena. Among the subspecialties that began to emerge toward the mid-to-late 1800s was biophysics, the application of physics to investigate biological phenomena. Although the actual origin of biophysics is uncertain, the invention of the battery; increased understanding of animal electrophysiology; and developments in electrochemistry, physical chemistry, thermodynamics, X-ray crystallography, and electromagnetic theory all contributed to the field we now call biophysics.

Origins

Scientific inquiry gradually matured through the ages, documented as far back as the ancient Egyptian and Babylonians, though less organized before Aristotle (384–322 B.C.E.) defined the scientific method. In science, perhaps more so than any other school of thought, knowledge builds upon knowledge. A seemingly inconsequential discovery could later inform a different investigation, bringing forth a clarification that would not have been possible otherwise. Biophysics was born from such disjointed discoveries in early experiments that had a narrow focus but later informed or provided a template for a methodology that could be modified to test a new theory. Examples of

these types of experiments were the discovery of bioluminescence in jellyfish and fireflies in studies by Athanasius Kircher, Isaac Newton's foray into the investigation of the nature of muscle movement (1687), and John Walsh's discovery, with Benjamin Franklin, of the electrical discharge from a torpedo fish or electric ray (1773).

Later in the 18th and 19th centuries, scientists became more interested in elucidating the force that produced movement in animals. The scientific method and experimental work concerning the nature of electricity and its role in animal life allowed scientists to ask questions that had not been possible to evaluate before. Most of the experiments conducted during this time were performed by professors of physics who were interested in describing biological phenomena. One such physicist, Abbé Giovanni Beccaria, professor of physics in Turin, performed experiments in which animal muscles received electrical stimulation. An English surgeon and professor of anatomy and physiology in Göttingen, Albrecht von Haller, hypothesized that electrical matter and "animal spirits" were the same.

Electrochemistry

Understanding the electrical component of muscle stimulation was facilitated by the experiments of Italian physiologist Luigi Galvani in the late 1700s. During an experiment, he had skinned a frog leg and was preparing to rub the leg to produce static electricity. His assistant probed the frog leg with a scalpel that unknowingly had a static charge. When the scalpel touched the leg, a spark of static electricity was produced, and the frog leg jumped. At the time, it was believed that electrical current within the animal produced a contraction and that the source was concentrated in the animal's pelvis.

In an effort to clarify the cause of the frog leg's response to the application of static electricity, Alessandro Volta, an Italian contemporary of Galvani, performed several experiments to reproduce the effects witnessed by Galvani. Volta believed that the frog leg only served as an electrical detector to the external electrical source. Meanwhile, those who sided with Galvani's explanation that the electrical source causing contraction was in the animal tissue, several

experiments were conducted that appeared to confirm Galvani's hypothesis. The animal muscle contracted when placed in contact with charged metals. However, Volta performed experiments using his invention of the voltaic pile, so called, a series of alternating silver or copper and zinc discs that had cloth or cardboard soaked in brine placed between the discs and arranged in a circuit, connected to the frog leg. He demonstrated that the contraction was produced by the contact with dissimilar metals, and the frog leg was only behaving as a detector.

Volta's experiments using the voltaic pile resulted in the invention of the early electrical battery. This invention was immediately recognized by the scientific and industrial community for potential uses, which seemed more important than understanding the electrical potential in animals. Study in the area of electrophysiology did not regain popularity until 1827 when the galvanometer, or an instrument for detecting electric current, was built by German electrophysiologist Emil Du Bois-Reymond. This instrument proved able to detect small potential differences across nervous membranes. A new branch of science, *neurophysiology*, developed from the data that were produced by the galvanometer. It is not unusual for physiology and biophysics experimentation to overlap yet remain distinct fields of study.

In addition to neurophysiology, biophysical experiments investigating diffusion gradients and osmotic pressure in living organisms became an important avenue of study. *Osmotic pressure* is the pressure that develops in a solution of salts when separated from pure solvent by a semipermeable membrane. This phenomenon was first described by Abbé J. A. Nollet, a French physicist. The semipermeable membrane was discovered by French scientist René Dutochet in 1828. The understanding of diffusion in biological systems was furthered by botanist W. F. P. Pfeffer, who obtained the first quantitative measurements. Adolf Fick then took the experimental data generated by Pfeffer and merged it with his understanding of the laws governing the flow of heat. He published the first biophysics textbook, *Die medizinische Physik* (Medical Physics) in 1856.

Additional applications of electrophysiology to biophysical experimentation were devised by the German physiologist Hermann von

Helmholtz (1821–1894), who studied both nerve conduction and the physiology of hearing. In 1849, he studied the speed at which an electrical signal was carried along a nerve fiber. Before this measurement, scientists were under the impression that nerve signals traveled faster than anything their available equipment could measure. He utilized the galvanometer developed by Du Bois-Reymond to act as a timing device. Helmholtz attached a mirror to a needle connected to a sciatic nerve of a frog leg, which reflected a light beam across the room to a scale. He was able to detect transmission speeds between 24.6 and 38.4 meters per second. This information enabled scientists to begin to develop better technologies that could capture transmission speeds of nerve conduction.

Developments in Physical Chemistry

Important to the later applications of molecular biophysics (most commonly practiced today) are the atomic theory, the first and second laws of thermodynamics, and advancement in reaction kinetics, which allowed scientists to describe the structural and functional properties of enzymes and proteins. In the early 1800s, the English physicist John Dalton proposed his atomic theory, which stated that matter was composed of discrete, indivisible atoms. It was later corroborated by Amedeo Avogadro in 1811, by making the distinction between atoms and molecules of a specific substance. At the same time, advancements in understanding about heat, energy, work, and temperature were made. The first law of thermodynamics, which states that heat and work are interchangeable, was proposed by the German physicist Julius Robert von Mayer in 1842. Almost 10 years later, the second law of thermodynamics was presented by the German mathematical physicist Rudolf Julius Emanuel Clausius and William Thomson, saying that when energy is transferred or changes from one form to another in a closed system, disorder (entropy) increases.

Chemical kinetics studies were bolstered by the developments made in the area of gas properties and laws. Between 1860 and 1875, Austrian physicist Ludwig Boltzmann and British physicist James Clerk Maxwell demonstrated that the ideal

gas law could be explained by the kinetic theory of matter. Subsequent analysis in chemical kinetics and the formulation of the laws of chemical equilibrium (e.g., Le Chatelier's principle) were based on the kinetic theory of matter. It was determined that the main factors that influence a reaction rate are the concentration, physical state, and temperature of the reactants, and whether there is a catalyst present in the reaction.

In 1864, Peter Waage and Cato Guldberg formulated the law of mass action, which states that the speed of a chemical reaction is proportional to the amount of the reactants. Also, it was found that in consecutive reactions, the kinetics are derived by the rate-determining step. This step represents the slowest step in the series of reactions and can be identified by the rate equation. Knowing the rate-determining step helps to optimize chemical reactions such as catalysis and combustion. This information was important to being able to test the thermodynamics of enzymes and proteins, which enable biophysicists and biochemists to characterize the function of both.

Advancements in optics were also important to the development and characterization of macromolecules, such as proteins that are crystallized (though this application was not practiced until the 20th century). In 1815, a French polymath named Jean-Baptiste Biot studied plane-polarized light (polarized light results from an electromagnetic wave being filtered so that it oscillates in just one plane of vibration rather than in several, unlike nonpolarized light such as light from the sun or from a candle flame); he focused polarized light on organic substances and noticed that the light could be rotated clockwise or counterclockwise, depending on the optical axis of the molecule. This knowledge contributed to determining the structure of proteins and enzymes by X-ray crystallography, which is a very important role that biophysics has played in the 20th and 21st centuries.

Late 19th Century

An increase in the understanding of thermodynamics and molecular structure helped to pave the way for future experiments in structural biology, which draws upon many physical and biological

disciplines to determine the structure of proteins. Scientists were particularly interested in studying the life-sustaining chemical reactions that happened in living cells. Among the important developments that helped to better understand molecular structures were stereochemistry and thermodynamics, as well as advancements in chemical theories.

In 1874, Dutch physicist Jacobus Hendricus van't Hoff established the foundation of stereochemistry with his experiments on optically active carbon compounds and was able to describe three-dimensional and asymmetrical molecular structures. *Stereochemistry* is the study of the spatial arrangement of atoms in a molecule and detection of a change in that arrangement when the molecule is manipulated (e.g. heated). A short time later, he began to apply the thermodynamics of chemical reactions, leading to defining the order of reactions. *Thermodynamics* is a component of physical chemistry that seeks to describe the physical properties of macroscopic systems—for example, enzymes and proteins. These physical properties consist of sensitivities to temperature, pressure, and volume, which are the classic parameters that are measured. In addition to these parameters, variables such as density, specific heat, compressibility, and the coefficient of thermal expansion can be evaluated to determine the full spectrum of physical characteristics and how a substance behaves in its environment.

Other scientists, such as Comte Claude Louis Berthollet, studied the rate and reversibility of reactions, and Benjamin Thompson, an American physicist, tried to elucidate the mechanical equivalent of heat. In 1875, Josiah Willard Gibbs presented the phase rule, which applies thermodynamics to heterogeneous substances. Swedish chemist Svante August Arrhenius produced the theory of electrolyte dissociation, later called *Arrhenius's theory*, in 1889. In 1906, the German physical chemist Walther Hermann Nernst produced Nernst's theorem, subsequently referred to as *the third law of thermodynamics*, which states that the entropy of a system at absolute zero is a well-defined constant. He also contributed to the advancement of physical chemistry by describing physical properties, molecular structures, and reaction rates of macroscopic molecules.

X-Ray Crystallography

One of the most important scientific modalities for biophysics of the 19th century (and beyond) was X-ray crystallography. Crystallography was invented to analyze crystals and their shapes in the 18th century. In 1784, René Just Haüy discovered that a crystal's face could be described in terms of stacking patterns of blocks of similar shapes and sizes. In 1839, William Hallows Miller was able to assign each facet of the crystal a unique three-integer label. Eventually, it was proven that all crystals are a regular three-dimensional array of atoms and molecules. By the 19th century, a complete catalog of possible symmetries of a crystal were constructed by Johan Hessel, Auguste Bravais, Evgraf Fedorov, Arthur Schönflies, and William Barlow. In the 1880s, a few crystal structures had been elucidated, though the structural information was not completely accepted due to the lack of techniques available to verify it (X-ray).

In 1895, Wilhelm Conrad Röntgen discovered the X-ray, though little was known about this form of electromagnetic radiation. Scientists were uncertain of the characteristics of X-rays but were able to reconcile some of the electromagnetic properties of X-rays according to the wave model of light (Maxwell theory of electromagnetic radiation). The visible wavelength of X-rays was determined by Arnold Sommerfeld to be approximately 1 angstrom. By 1905, Albert Einstein had discovered that X-rays were not only waves of electromagnetic radiation but also photons and exhibited particle-like properties. It was observed that when an X-ray is directed toward a crystal, the electron density in the crystal will cause a scattering of light that is characteristic of the arrangement of the electrons within the structure. Based on these scatter patterns, a structure can be determined mathematically. However, this approach to solving the structure of a molecule did not become prevalent until 1912.

Electromagnetic Theory

Electromagnetic theory is important to the field of biophysics because it provides another avenue to observe crystal structures. Up until the late 1800s, electricity and magnetism were considered separate forces. However, when James Clerk

Maxwell published his 1873 *Treatise on Electricity and Magnetism*, he presented the observation that interactions of positive and negative charges seemed to be moderated by a single force. There were four points to his argument: (1) Electric charges attract or repel each other with an inversely proportional force multiplied by the square of the distance between them (opposite charges attract each other); (2) magnetic poles attract or repel based on their charge and occur in pairs; (3) an electric current in a wire generates a circular magnetic field around the wire, and its direction followed that of the current; and (4) a current is created in a loop of a wire when it is pulled away or toward a magnetic field, and follows the direction of the current. This observation helped to advance our understanding of electromagnetic forces, which led to the development of nuclear magnetic resonance (NMR). NMR allows for determination of the structure of solid materials at high resolution. Additionally, elucidation of intermolecular forces generated by the momentum of an electron's movement was made possible. Scientists in the 20th century were able to employ technological advances such as NMR in determining the structure of organic molecules or substances difficult to crystallize, compared with that observed by X-ray crystallography.

BIOPHYSICS, 20TH CENTURY

Biophysics is a branch of science that integrates several disciplines (physics, chemistry, and bioengineering) to study biological systems. It is applied to the molecular scale, in determining structures of nucleic acids and proteins; to whole organisms, and even ecosystems. One advantage of biophysics is the ability to set up experiments that elicit exact hypotheses and interpretations. The biophysicist is likely to be the first to employ new technologies (e.g., NMR, nuclear magnetic resonance) to apply complex physical theory to the problems posed in biology.

Another advantage is that the application potential of biophysics to the natural world seems endless. A challenge for the student of biophysics, however, is the disparate opinions on what exactly biophysics is. There is scientific equipoise on the actual definition of biophysics, as it spans so many different applications.

However, despite the disagreement among biophysicists on what biophysics really means, there are areas of application that can be used to categorize the contributions that biophysics has made in the 20th century, leading into the 21st century. Astrobiophysics studies the influence of astrophysical phenomena upon life on planet Earth. Medical biophysics uses the advances in biophysics methodologies for diagnostic and therapeutic purposes. Molecular biophysics is the most rapidly evolving version of biophysics; it characterizes biosystems, molecular structures, dynamic behavior of proteins (single molecules up to supramolecular structures), and viruses. Detlev Wulf Bronk, a renowned American physicist and administrator, established

biophysics as a distinct scientific discipline toward the middle of the 20th century.

Over the decades that followed, as technological advances were made, so too did the selection of instrumentation and equipment help to overcome a difficulty in experimentation. Some of the biophysical methods used to study biological systems include X-ray diffraction, chromatography, macromolecular crystallography, proteolysis, NMR spectroscopy, electron paramagnetic resonance, cryo-electron microscopy, multi- and small-angle light scattering, ultrafast laser spectroscopy, dual polarization interferometry, and circular dichroism.

Notable Inventions

One of the most important tools used to determine the structure of a macromolecule is *X-ray crystallography*. By the early 1900s, physicists were beginning to understand the possible scope this technique could have; most certainly, it was the best tool for gathering atomic data on crystals. These data could be mathematically plotted and analyzed for determining the shape of a substance, as long as the substance could diffract. Not just any substance can diffract light. Certain types of surfaces are better for diffraction than others (e.g., jagged edges diffract better than smooth edges). In 1924, while at Cambridge University, British physicist Jon Bernal solved the structure of graphite and worked on solving the structure of bronze. One of his more distinct and wide-reaching inventions was an *X-ray spectrogoniometer*. A goniometer is an instrument that allows an object to be rotated and measured at different angles. For X-ray crystallography, goniometers are used for measuring angles between crystal facets as well as rotating the sample.

NMR spectroscopy is a technique that measures the energy that resonates in a specific frequency within a magnetic field. It was first developed in 1938 by Isidor Rabi, who later won a Nobel Prize for this invention. It is used to collect physical, chemical, electrical, and structural specifics about molecules. It can provide information about topology, dynamics, and the three-dimensional structure of a molecule in solution or in a solid state. One of its strengths is that it is selective in regard to types of atoms studied within a molecule.

Molecular modeling is the array of methods that are used to investigate the dynamics, surface properties, and structure of biomolecules. Beginning with the modeling of the double helix of DNA (deoxyribonucleic acid, which carries genetic instructions for the development of all known organisms and many viruses), many other molecules and their properties have been modeled such as protein folding, enzyme catalysis, protein stability (thermostability assays), and producing conformational variants (open, intermediate, or closed states).

Patch clamp and single-channel recordings enabled both electrophysiologists and biophysicists to study multiple channels or single-ion channels and determine the effects of these channels on different stimuli. The stimuli could be anything from protons to chemicals, or ligands that are introduced via a special apparatus that controls the rate of flow over a cell. The electrical potential is then measured in amperes and assessed for length of the channel being in open or steady-state conditions. Using these data, dose-response curves can be generated for a particular drug that is introduced to the receptor on the cell's surface.

The *Ramachandran plot* was created in 1963 by biophysicist G. N. Ramachandran and colleagues in order to visualize backbone dihedral angles against amino acids in a protein structure. Today, the plot is generated using X-ray diffraction data for a sample protein and compares the distribution of data points from the sample to that of a known protein structure (structure validation). This task is more easily accomplished if there is a known structure within a family of proteins.

In the late 20th century, *condensed phase single-molecule fluorescence spectroscopy* was devised by W. E. Moerner and Lothar Kador. It uses the fluorescence of a molecule to derive measurements about its structure, position, and its environment. Its strength is that it allows the investigator to obtain information without losing important values due to ensemble averaging. When performing recording techniques, such as patch clamp electrophysiology, the signal that is obtained from the recording of many molecules at the same time is considered the average property of the molecule's dynamics. By focusing on one molecule, it is possible to obtain two-state trajectories.

Nerve Impulse

Following the animal experiments conducted by late-19th-century biophysicists, a prominent English biophysicist, Archibald Hill, performed significant work in the area of nerve conduction and enzyme kinetics. He is known for expanding Michaelis–Menten kinetics and authoring the Hill coefficient; the latter characterizes the binding cooperativity for enzymes and molecules. His work in heat generation by contracting muscles was conducted in 1920. He focused on studying the effects of electrical stimulation to muscle, the mechanical efficiency of muscle, muscle recovery through energy processes, interaction between oxygen and hemoglobin; and produced drug response curves from muscle. He was able to show that electrical activity was most robust in the presence of oxygen, and that during recovery the amount of oxygen required over resting was equivalent to 20% of the lactic acid produced during exercise. This amount of oxygen was needed to resynthesize lingering lactic acid into glycogen.

After World War II, the development of electronics vastly expanded, including radar technologies and the use of nuclear reactors in peacetime to produce large quantities of radioactive isotopes. Alan Hodgkin and Andrew Huxley utilized these advances and data from earlier studies in animal physiology (e.g., Julius Bernstein's membrane theory of nervous conduction), to produce a mathematical model that explains how action potentials are initiated and propagated in neurons (1952). They received the Nobel Prize in Physiology or Medicine in 1963 for such a groundbreaking and important work. Another post-World War II invention, the *electron microscope*, allowed the description of a muscular contraction at the structural level. Many advances in X-ray technology and electron microscopy have made it possible to observe and characterize many molecules that are involved in muscular contraction.

Sensory communication is another area that biophysics has impacted by technological advances that allow scientists to be able to measure stimulus, namely computerized equipment that is far more sensitive than earlier instruments. In general, quantitative analyses of sensory responses are difficult due to the multiple cell types involved. Before the advent of the computer in the 1970s,

Georg von Bekesy, a Hungarian physician, performed experiments with cadavers on the human ear. He dissected the inner ear of the cadaver while leaving the cochlea partially intact. Then he used strobe photography and silver flakes as a marker (which the black-and-white film easily detected) and was able to witness the surface wave of the basilar membrane when stimulated with sound vibrations.

Molecular Biophysics

American scientist Alexander Hollaender founded the study of radiation biology and produced early evidence of nucleic acid as the genetic material. In 1939, Hollaender published data showing that the absorption spectra of nucleic acids of a mutated ringworm fungus was the same as isolated nucleic acids, and therefore concluded that nucleic acids must be the building blocks of genes. However, his discovery was not immediately accepted until other experiments corroborated his hypothesis. It is with this information that a spectrophotometer can be used at a certain wavelength (260 nm) to detect and quantify the amount of DNA in a sample. This type of technology is used routinely in biological laboratories today.

Robert Brainerd Corey, American biochemist, is mostly known for his role in the discovery of the α -helix and the β -pleated sheet with Linus Pauling. In 1950, Pauling and Corey discovered that secondary conformations of peptides were arranged in such a way that their hydrogen-bonding capacity of the backbone NH (amine) and CO (carboxyl) groups was facilitated. First described was the α -helix, a rod-like shape that was composed of a tightly coiled backbone in the inner part with the side-chains extended outward forming a helical pattern. The coil is stabilized by the NH and CO groups of the primary structure. All of the main-chain NH and CO groups are hydrogen bonded. The angles were described in terms of angstroms (distance from one atom to another) and pitch (screw-shaped pattern). Later, the duo discovered another facet of secondary structure, the β -pleated sheet. This pattern differs markedly from the α -helix, taking an accordion-like appearance. In the beta sheets, beta strands, which are polypeptide chains of about three to 10

amino acids long, connect laterally by two to three hydrogen bonds in the backbone.

In 1953, biophysicist Francis Crick and biochemist James Watson determined the structure of DNA, one of the most important discoveries of modern science. Advancements in the use of X-ray diffraction for the determination of crystal structure offered the opportunity to investigate the molecular structure of DNA and RNA. Together the two utilized Chargaff's rule (which stated that for every adenine (A) there is a thymine (T) and for every cytosine (C) there is a guanine (G)) in conjunction with the X-ray crystallization data from Rosalind Franklin and Maurice Wilkins, to determine that the DNA structure was a double helix. There have been some minor changes in the model since it was published, but four of the major features still hold true: (1) DNA is a double-stranded helix, (2) most DNA helices are right-handed, (3) the double helix is antiparallel, and (4) the DNA base pairs are connected through hydrogen bonding, as well as the outer edges of the exposed nitrogen-containing bases. The methods used by Watson and Crick to determine the DNA structure are now used for model building in biophysics.

Donald L. Caspar, an American scientist, made significant contributions in structural biology, X-ray, neutron and electron diffraction, and protein elasticity. In 1962, Caspar and Aaron Klug introduced the concept of quasi-equivalence to account for the arrangement of proteins on the surface of icosahedron virus particles. Caspar-Klug theory has played an important part in shaping the subsequent study of viruses and other macromolecular assemblies. The original concept was based on electron microscopic studies and has now been refined to take into account the atomic resolution structure of viruses, and other details of protein-protein interactions that crystallography has elucidated. Quasi-equivalence continues to be an important component of the philosophical basis for how we think about macromolecular assemblies.

In the 1980s, Adriaan Bax, a molecular biophysicist, developed the field of biomolecular NMR spectroscopy, and he is responsible for many of the standard methods in the field. He pioneered the development of triple resonance

experiments and technology for resonance assignment of isotopically enriched proteins. He was also heavily involved in the development of using residual dipolar couplings (dipole-dipoles) and chemical shifts for determining RNA and protein structures. Recent work focuses on the roles of protein in membranes. He is one of the most cited and important scientists in the field of biomolecular NMR research. Direct dipole-dipole coupling is useful for molecular structural studies. The estimation of the coupling allows for a direct spectroscopic translation of the distance between nuclei and the geometrical form of a molecule. However, in isotropic solution, dipole-dipole couplings are absent as a result of rotational diffusion.

Gary Ackers, Emeritus Professor of Biochemistry and Molecular Biophysics at Washington University, focused on the thermodynamic linkage analysis of biological macromolecules, addressing the molecular mechanism of cooperative O₂ binding in human hemoglobin, beginning in the early 1970s. Briefly, cooperative binding occurs when a substrate binds to an enzymatic subunit (often protein molecules are a series of homogenous or heterogenous subunits that connect on the cell membrane to form one unit) and then activates the remaining subunits. Cooperativity can be positive, negative, or absent. Positive cooperativity results when oxygen binds to hemoglobin. The ratio of oxygen to ferrous iron in a hemoglobin molecule is one-to-one. Deoxy-hemoglobin has a low affinity for oxygen, but when one molecule of deoxy-hemoglobin binds to a heme site, the molecule's overall affinity for oxygen increases. Once this occurs, more oxygen molecules can bind to the hemoglobin molecule. Conversely, in negative cooperativity, when a ligand binds to a protein, the affinity for the ligand will decrease. The affinity for a ligand can be measured by plotting the amount of binding over the course of time.

In standard gel electrophoresis, which separates DNA molecules, there was an issue in that large DNA molecules (larger than 20 kb) would migrate together and it was difficult to obtain adequate resolution or detect the correct size DNA bands. Charles Cantor, an American molecular geneticist, along with David Schwartz, developed pulse-field gel electrophoresis for very large DNA molecules. This technique works by using an alternating

voltage gradient to resolve larger DNA molecules. Opposed to standard gel electrophoresis that runs unidirectional, the pulse-field gel's voltage is pulsed in three directions. The process takes longer than standard gel electrophoresis. Other contributions by Cantor and his lab at Boston University include methods for separating DNA molecules, increasing sensitivity for detection of proteins, and enabling the study of complex protein and nucleic acid relationships.

Pamela J. Bjorkman, an American biochemist, focuses her study on the three-dimensional structures of proteins related to Class I MHC, or major histocompatibility complex, which are proteins of the immune system. Bjorkman and her students study protein interactions involved with immune recognition, using techniques such as X-ray crystallography and confocal or electron microscopy.

Biological Membranes

Membrane biophysics is study of biological membrane structure and function by mathematical, physical, computational, and biophysical methods. In tandem, the data from these methods can be used to generate phase diagrams of various membrane types, describing their thermodynamic characteristics. In contrast to membrane biology, membrane biophysics provides quantitative information and accurate modeling of a variety of membrane topological presentations, such as protein-lipid coupling, lipid and cholesterol flip-flop rates, and lipid raft formations. Also, elasticity of the biological membrane and its intracellular effects can be studied.

One of the methods for visualizing a membrane surface is by attaching a radioactive compound that can either be introduced by insertion by recombinant techniques or added to a solution to bind to a specific receptor. In the early 20th century, the Danish physiologist August Krogh set the foundation for using radioisotopes in molecular biology. His understudy, Hans Ussing, described the pathway that allows the transport of ions across membranes to be explained. He is responsible for the discovery of the active transport of water and ions across a cell membrane. However, the complete molecular mechanism for how this is achieved is still poorly understood.

Despite the great progress in understanding mechanisms of how molecules are assembled into larger biomolecules, there remains a deficit in understanding of exactly how molecules are assembled into biological membranes. The way in which a membrane is constructed is extremely complex and requires better technology to gain useful insight.

Structural Biology

Structural biology is a branch of molecular biology that combines the disciplines biology, biochemistry, and biophysics. The main objective is to obtain a molecular structure of macromolecules, such as nucleic acids and proteins. In addition to structural information, functional data are elucidated through experiments such as electrophysiology. The proteins are usually evaluated in their most complex structures (tertiary and quaternary) and native states because proteins are functional in these states. When a protein is not in these states, inactivation occurs. A great deal of structural biology is centered on determining the structure of receptor proteins that function within a specific disease pathway or has an important physiological role. Often these proteins are crystallized in a specific condition and ligands (or specific compounds that bind to the receptors) are added that will allow the structural biologist to observe the changes in conformation that take place while the ligand is bound. If available, the ligand is a known drug that has a high affinity to the receptor that will promote a physiological response or block it.

Between 1982 and 1985, the German biochemists Johann Deisenhofer, Hartmut Michel, and Robert Huber determined the first crystal structure of an integral membrane protein, the photosynthetic reaction center. It is a membrane-bound complex of proteins and cofactors that play an important role in photosynthesis. They achieved this through X-ray crystallography to determine the exact arrangement of more than 10,000 atoms that make up the protein complex. Not only did their research increased the general understanding of the mechanisms of photosynthesis, but seeing a structure solved for an integral protein was important to help other biophysicists piece together new protocols for their own projects.

Helen M. Berman, an American biophysicist, is the director of the RCB Protein Data Bank. Her biophysics work includes structural analyses of protein–nucleic acid complexes and the role of water in molecular interactions. The Protein Data Bank is an online repository for three-dimensional structural data of large biomolecules (proteins and nucleic acid). The database houses hundreds of protein structures. This online repository is the premier source of data for structural biologists. Most of the data commonly reported with the structure is X-ray diffraction or NMR data. Scientists from around the world are able to submit their structures and are able to download structural data for comparison with their own models. This enables scientists to adjust their models or raise questions about existing structural models.

Steven M. Block (Stanford University) pioneered the use of optical tweezers, a technique developed by Arthur Ashkin, to study biological enzymes and polymers at the single-molecule level. Optical tweezers are instruments that use a highly focused laser beam that attracts or repels according to the refractive index mismatch. This technique has been highly utilized in modern biophysics. The ability to control single molecules with nanometer precision and piconewton accuracy has allowed scientists to directly test the effects of DNA binding on DNA properties and to test the interactions involved in these systems. Understanding the complex mechanisms involved in biological processes is very important and has the potential to improve therapeutics and other molecular biology methodologies.

Related to optical tweezers and single-molecule fluorescence, visualization techniques such as scanning-force microscopy have allowed biophysicists to study the structure and function of nucleoproteins. Carlos Jose Bustamante is an American molecular biologist who pioneered use of optical tweezers and scanning-force microscopy. His laboratory focuses on developing methods of using single molecules to characterize the elasticity of DNA, to induce unfolding of individual protein molecules, and to probe the mechanical behavior of molecular motors.

Axel T. Brünger is known for developing a computer program used for solving structures based on X-ray diffraction data or solution NMR

data. The program is widely used because of its various features. The program is a major extension of the program his team developed called *PLOR*, which came out in 1987. The program utilized a method called *simulated annealing* to refine X-ray crystal structures. It was a manually intense process. When Brünger introduced simulated annealing crystallographic refinement in his 1987 paper, the time to refine crystal structures was significantly reduced and it had a tremendous impact in the crystallographic community.

In some families of proteins, such as the G-protein-coupled receptors (GPCRs), the majority of receptors' structures have been solved. These receptors sense molecules outside the cell and activate signal transduction pathways, which lead to cellular responses. They are difficult to crystallize because there are seven transmembrane receptors that pass through the cell membrane. There are six classes of GPCRs that are homologous and functionally similar. Much information has been obtained regarding their roles in signaling and ligand-binding.

Computational Biology

Predicting the three-dimensional structure of a protein from its amino acid sequence can be a daunting task, especially when there are no homologous structures to compare a new protein structure with. Structure prediction is diametrically opposite from protein design. Protein prediction is one of the most important goals of structural biology. By knowing the structure, it is possible to design drugs that will have greater specificity with the receptor target, thereby causing less side effects overall. Also, enzymes can be created that have biological or industrial uses. In order to help remove some of the obstacles in protein prediction, a number of bioinformatic programs have been created that allows the user to do more tasks at a time.

Some example of molecular design software are Pymol, AMBER, Ascalaph Designer, BOSS, DOCK, Firefly, Maestro, SCIGRESS, SPARTAN, and TINKER. Pymol is an open-source molecular visualization program that was created by Warren Lyford DeLano. It is most commonly used to produce high-quality three-dimensional images of an array of biomolecules. It is one of the only

open-source visualization programs available to structural biologists. It is programmed in the Python programming language.

David Baker is the principal investigator of the 60+ member Baker laboratory. He and his team developed the Rosetta algorithm for *ab initio* protein structure prediction, which is associated with the computing project called *Rosetta@home* and *Foldit*. Members of the Baker group also focus on protein design; they are the first group to have designed a protein, named Top7, with a unique fold. Baker received the 2008 Sackler International Prize in Biophysics for his work in protein folding.

Newer Applications of Biophysics

Astrobiophysics

Astrobiophysics is another emerging application of biophysics that utilizes data obtained from many diverse fields of study, such as biochemistry, paleontology, atmospheric science, and astronomy. Dr. Brian Thomas and his research team at Washburn University (Kansas) apply these principles to study how the Earth is affected by radiation from space. There are several projects underway, most notably the study of the impact on Earth of a nearby supernova. The project uses computational modeling to observe the combined effects of atmospheric ionizations and radiation impact on land and sea life. The presence of the isotope iron-60 in sediment cores bears witness to the fact that a near-Earth supernova occurred within the last 2 million years. The discharge from the event was close enough to change the atmospheric UV levels and possibly modified the Earth's climate. Their work continues in hopes of gaining insight into what sort of impact could a future near-Earth supernova pose to life on the planet.

Medical Biophysics

A fairly new (2013) application of the biophysics discipline is in the field of medicine. There are many classic biophysicists who use methods for determining structures of molecules, membrane surfaces, and proteins in hopes of treating diseases

or better understanding a particular disease pathway. Medical biophysicists employ the findings of these studies in the treatment of patients, in addition to using scanning equipment (e.g., NMR). Individuals who are interested in this new area of study have only a few institutions (Canada and Europe) that offer coursework explicitly aimed at medical biophysics. In the United States, graduate-level programs usually offer PhDs or dual degrees (MD/PhD) in physiology and biophysics, but the interest is growing.

It is easy to see from the history of various disciplines that a consensus on the definition of what biophysics is difficult to achieve. At best, biophysics supplies molecular biology with highly precise quantitative measurements in biophysical processes that could otherwise not be determined. Although its early emphasis was on physiological problems such as nerve conduction and sensory communication (the ear), there was a clear movement toward molecular biology after Watson and Crick used X-ray diffraction data to determine the structure of DNA. It was understood that the future of science leaned heavily toward elucidating the mysteries of biology. It is now the case, however, that all molecular techniques are used in every biomolecular area of study.

The current emphasis for biophysics is in the area of structural biology. The last 20 years of structural biology has been replete with determining novel structures, often the only member of a protein family, and have facilitated the determination of structures in other members of a protein family. The other half of structural biology, the development of novel proteins and enzymes, has implications for cancer treatments or genetic therapies. These therapies and diagnostic methodologies have paved the way for newer fields applying biophysics such as medical biophysics and even astrobiophysics (ecological impacts). These applications seem to be where the future lies for biophysics and likely will be so in the next decade and beyond.

BIOPHYSICS, CONTEMPORARY

Biophysics is the application of physical concepts and methods toward understanding the living world. As in other branches of physics, experimental biophysical investigation is tightly coupled to the construction of theoretical models that form a mathematical narrative for the phenomena under study, and which help guide and interpret experiments. Whereas 20th-century biophysics largely followed a reductionistic approach, focused on understanding isolated biomolecules and biomolecular processes, contemporary biophysics frequently seeks to understand whole cells, organisms, and communities as self-organized systems, whose properties reflect the combined influence of selective evolutionary pressure and physical constraints.

Theory in Biophysics

Physics aims to form a narrative for all natural phenomena. This narrative takes the form of theoretical models, which are used as everyday tools in physicists' hands to formulate hypotheses and to guide and interpret experiments. Beyond the critical requirement of providing predictive power toward future experiments, a theoretical physical model must exhibit several other characteristics to be considered satisfactory: (a) It must be *quantitative*, expressed in mathematical equations rather than in words, pictures, and so on, which are acceptable formulations for theories in some other disciplines. (b) It must be *simple*. Following Occam's razor, a model is considered better if it has fewer equations and parameters. (c) At the same time, a physical model should also be *universal*, explaining multiple diverse phenomena.

An example of how these requirements can be simultaneously fulfilled is Isaac Newton's law of gravity, whereby the same mathematical equation can be used to calculate the trajectory of an apple falling from a tree, a rocket flying to Mars, or planets orbiting the sun. And in the centuries since Newton's time, theoretical models guided by these same criteria have been developed to describe inanimate matter across scales, from the subatomic to the cosmological. *Biophysics* seeks to extend these efforts to living matter, such that we can understand and predict the behavior of living systems using a quantitative, simple, and universal narrative. It must be noted at the outset that, compared to theories of nonliving systems, the biophysical effort is in an infinitely more primitive state—akin, perhaps, to where the rest of physics was in the 17th century, with (as Newton said) the great ocean of truth lying all undiscovered before us.

In the 20th century, biophysical investigation largely followed a reductionist approach, applying known physical theories to understand the properties of biomolecules, such as DNA, proteins, and lipids, and biomolecular processes, such as the folding of proteins into their functional three-dimensional conformations. In the early 21st century, these theoretical interrogations continue to gain power owing to rapid progress in enabling experimental techniques, such as cryogenic electron microscopy and fluorescence microscopy, and computational methods, such as molecular dynamics simulations and machine learning tools. Altogether, these advancements enable molecular biophysics to move from the study of isolated molecules in an aqueous solution to examining more elaborate scenarios, where multiple molecular species interact in a chemically complex environment, thus beginning to emulate what takes place in the living cell rather than in a laboratory test tube.

The Physics of Living Systems

A complementary approach to biophysics, which was always present in the field but gained prominence in the 21st century, focuses not on the isolated constituents that make up living matter, but rather on how these constituents come together to form *living systems*—cells, organisms, and communities. This effort is inspired by, and

aims to emulate, the success of statistical physics to predict how macroscopic properties of inanimate matter emerge from the interactions between its microscopic constituents. This theoretical success was originally limited to simple materials that are homogenous and orderly, such as crystals, but gradually grew to include more complex systems that are heterogenous and disordered, such as glass, or out of equilibrium (i.e., undergoing change) such as weather phenomena. Extrapolating from this success, living systems are viewed as the ultimate emergent phenomena, and understanding them as the natural next step in the study of complex systems.

Theories in this area of biophysics (sometimes called *physics of living systems*) thus seek to explain how biomolecules self-assemble into machines, complexes, and networks that underlie the function of the living cell; how individual cells likewise organize to form a brain, an immune system, and the other multicellular structures that make up a higher organism; and how organisms again self-organize into communities and ecosystems. Moreover, beyond the understanding of living systems as a subject matter, developing such theories will lead (it is hoped) to the discovery of new physical principles—*laws*—governing the process of self-organization. Thus, this branch of contemporary biophysics goes beyond the traditional strand by anticipating new physics from biology, rather than only new biology through physics.

But applying the statistical-physics paradigm toward understanding biology faces considerable obstacles, reflecting the unique properties of living systems as compared with their inanimate counterparts. First of those is the absence of *scale separation*. In traditional physics, different spatio-temporal scales can often be considered separately. For example, when describing the flow of liquid at the macroscopic scale, one can ignore the atomistic nature of material at the microscopic level. This conscious ignorance is enabled by the theoretical practice of coarse graining, where a multitude of details on a lower scale (e.g., the complex interaction between nearby molecules of the liquid) is mapped to much fewer observables on the higher scale (the resulting viscosity of the liquid). Matters are very different in biological systems, where critical information is

typically present at all spatial and temporal scales, from the conformational changes of individual biomolecules at the nanometer and nanoseconds range to the resulting changes in characteristics (phenotype) of a multicellular organism, taking place over meters and hours. Consequently, there is no standard procedure for coarse graining over the molecular details of a living system when aiming to describe it at the cellular, or higher, level. This poses a significant obstacle on the way to constructing a simple theoretical narrative in the physical tradition.

To make matters worse, the detailed information required for constructing a biophysical model is simply unavailable for the vast majority of molecular processes in the cell. Even in the best studied organisms, which serve as *model systems* for the rest of the living world, what typically exists is a partial list of molecular players involved in a given process (e.g., the transcription of RNA molecules from their DNA template), but none of the biophysical parameters—binding affinities, reaction rates, and so on—that characterize the underlying molecular interactions. Even for the handful of select processes on which researchers have focused over decades—for example, how the activity of a specific sugar utilization gene in *Escherichia coli* bacteria is regulated—what is mostly available are measurements made on isolated molecules in a laboratory test tube. The relevance of these measurements to the complex intracellular environment, where physical conditions are very different, and where numerous additional players are present, is uncertain. The bottom line is that, even if building a detailed molecular model for everything in the cell were computationally feasible, the information required for constructing such models is still missing.

Minimal Mechanistic Models and Occam's Rug

To circumnavigate these obstacles, simple theoretical models for biological phenomena are often constructed by trying to identify a minimal set of features that are essential for the observed phenomenon—and are therefore explicitly included in the mathematical representation—while ignoring many other details. The choice of which details to

ignore reflects a conscious decision by the biophysicist, but also, invariably, the fact that (as noted above) those details are largely unknown. In addition, identifying which features to include in the model is often done via trial and error by testing what choices improve the agreement between theoretical predictions and experimental observations. Owing to this targeted process of model construction, such models are more properly considered phenomenological (top-down) rather than truly reductionistic (*bottom-up*). Another hallmark of these simplified models is referred to as *Occam's rug*: In contrast to the physics of nonliving systems, where a simple theory is thought to bear the hallmark of truth (Occam's razor), in the case of biophysics, a model's simplicity instead implies that most of the details have been swept under the rug.

The minimal modeling approach has proven powerful when applied to biological phenomena that are relatively simple and well characterized, with the canonical examples coming from *E. coli*, the best studied of all model organisms. Mechanistic biophysical theories have been formulated to capture the way a bacterial cell senses changes in its chemical environment and modulates its behavior accordingly, by swimming toward nutrients and by producing the enzymes required for consuming these nutrients. Following the earlier success in bacteria, the first decades of the 21st century have seen an explosion of minimal mechanistic models directed at systems of higher biological complexity, including processes taking place in eukaryotic (nucleated) cells, during embryonic development of multicellular organisms, and during the onset of human disease, such as the emergence of cancer.

Unfortunately, evaluating the success of biophysical models is less straightforward than it is for models of inanimate matter. This is because, as noted above, the construction of biophysical models involves cherry-picking what features to include, and, consequently, the resulting models are rarely unique mathematically or biologically. In other words, the fact that a given theory recreates existing data does not necessarily mean that it correctly captured the essential biological features. This problem is made more severe by the fact that matching theory and experiment almost invariably involves the process of fitting unknown

mathematical parameters. These parameters represent biophysical properties of the system, such as molecular concentrations and diffusion and reaction rates, but since their values are unknown, they become ad hoc correction factors that artificially increase the model's chances of success. This weakness of mechanistic biophysical models often reveals itself in their limited predictive power outside the narrow premise for which they were calibrated, thus failing the premise of universality desired in physical theories.

Modeling Cellular Individuality

Both the success and limitations of minimal biophysical models are demonstrated by the question of single-cell behavior. It has long been observed that individual living cells, even if they are genetically identical to each other and placed in the same environment, nevertheless may exhibit large differences in the expression of their genes and, consequently, their phenotype. This cellular *individuality* has important consequences across biology, from the emergence of resistance to antibiotics among bacteria to the choice of cellular identity during early embryonic development. The individuality of cells places an additional challenge for biophysical models: beyond capturing the average behavior of a cell population, also predicting the cell-to-cell differences in this behavior.

Attuned, perhaps, to the contemporaneous zeitgeist emphasizing heterogeneity over uniformity, biophysical theory turned its attention to cellular individuality during the late 20th century. To do so, it called on the concept of *noise*, as used in the study of electronic communication, where it indicates random, unwanted fluctuations that accompany the transmitted signal and may obscure it. In the cellular context, noise—the deviation of single-cell properties from the expected average behavior—arises from the inherent randomness of biomolecular events such as diffusion and binding, which in turn results in cell-to-cell differences in the production of regulatory molecules and, consequently, in phenotype. The physical theory of stochastic processes provides the tools for calculating the expected degree of cellular heterogeneity, in the form of the statistical distributions of any quantity, for example, the numbers of proteins

produced from a gene. This theoretical approach has proven successful in reproducing experimental measurements of gene expression in individual bacterial cells, and it has since been expanded to describe other facets of cellular individuality.

But utilizing the concept of *noise* to describe cellular heterogeneity also comes with a strong caveat. A key implication of the stochastic picture is that single-cell behavior is inherently unpredictable, and that a living cell's every choice is subject to significant randomness. However, by implying that single-cell observables are not merely unknown but also *unknowable* (in that they are unpredictable), the noise idea legitimizes our ignorance of these cellular properties, sweeping them too under Occam's rug. A stochastic description of cell behavior may thus create a facade of understanding, while in fact impeding the efforts to reveal deterministic drivers of that behavior. Conversely, forgoing the assumption of randomness and identifying those *hidden variables* (a term borrowed from quantum mechanics) will allow biophysical theories to regain predictive power at the single-cell level. The search for hidden variables that drive cellular individuality is an active area of study.

Beyond Mechanistic Models: Evolved Optimality Under Physical Constraints

A complementary approach to developing a theoretical description of living systems posits that these systems' overwhelming complexity, and our considerable ignorance of the underlying molecular details, should argue against the construction of mechanistic models. Instead, biophysical theories should leverage the one universal law of biology already known to us, namely, evolution. Specifically, the premise of theoretical analysis should be that the observed properties of any biological system reflect the outcome of selective pressure to optimize its function, as the system evolves under a set of physical constraints. This investigative approach, typically referred to as *systems biology*—although that term carries different meanings to different people—is highly interdisciplinary. In addition to physics, it leverages theoretical tools from fields as remote as information theory (originally used to describe the

communication of digital information), control theory (used to describe human-made devices), economics, and other areas where the question of optimal performance in the presence of external constraints is often of interest.

Systems biology has had multiple successes in identifying and explaining the properties of living systems. One example is the discovery of common topological features in biological networks. These network *motifs*—typical patterns of connectivity between network nodes—optimize the processing of information by the network. Strikingly, the same motifs are found across systems as disparate as the genetic circuits within a cell and the neuronal networks in the brain, as well as the (human created) World Wide Web, all of which share the requirement to transmit information efficiently to function properly. Other types of motifs endow networks with the property of *robustness*, defined as the ability to function in the presence of uncontrolled fluctuations of both the environment (e.g., changes in temperature) and of the system's internal components (e.g., varying numbers of cellular proteins). Applying principles from control theory led to the identification of robustness in the biochemical networks that underlie bacteria's ability to sense and swim toward nutrients, and in genetic circuits that drive the early stages of embryonic development. In another example of using a systems biology approach, researchers utilized the economic principle of *Pareto optimality*, which describes how trade-offs between different tasks can be best reconciled, to explain several quantitative relations observed across biology, from the shapes of Darwin's beak of the finch, and the sizes of bat wings, to the sets of genes bacteria express under changing growth conditions.

As exemplified by the cases above, the theoretical models of systems biology often constitute a satisfactory physical narrative, in being relatively simple but at the same time universal—that is, applicable across diverse biological instances. But this attractiveness does come with a price tag. For one, while a self-consistent explanation for the observed phenomenon is offered, the underlying mechanistic details (the *how*), which invariably differ between biological systems, often remain unknown. Another aspect sometimes missing from these theories is novel predictions regarding future

experiments; for example, the expected response to specified perturbations. Such predictions are required as means to falsify the proposed theory, which, in their absence, risks becoming more of a *Just So* story.

Concluding Remarks

In evaluating contemporary biophysical theory, it must be noted that, even for the best characterized living systems, we are still very far from achieving a comprehensive *molecules to organisms* narrative that fulfills the simultaneous requirements of quantification, simplicity, and universality. An honest assessment of the field must question whether such models are even an achievable goal. Put differently, beyond important but limited *niches*, such as illuminating the function of biological molecules, what roles can physical theories play in understanding the living world? Of course, one may simply argue that physicists' interest in pursuing theoretical interrogation of living systems is sufficient justification for the endeavor. After all, we must remember that intellectual curiosity has always been the driver of discovery. Moreover, the biophysical endeavor has significant pedagogical value, as it involves the training of interdisciplinary scientists capable of applying rigorous quantitative analysis to biological and medical problems. On the other hand, if one considers that the role of theory is, above all, to provide predictive power—here, forecasting the future behavior of a living system under previously untested conditions—then, in the 21st century, it may be argued that a more promising avenue to achieving that power is offered by machine learning, whereby a computerized algorithm learns from past information to predict future data, without going through the *middleperson* of a human-curated model. But a more balanced view suggests that model-free prediction can provide benchmarking for the performance of human-created models, benchmarking which physicists never had before. Furthermore, machine learning methods can aid in the construction of theoretical models, by helping to delineate critical from ignorable features, and to identify model rules that predict experimental observations. Thus, rather than harbinger of a future of *prediction*

without understanding, machine learning methods promise to become an invaluable tool in the theoretical arsenal of biophysicists.

BIOPSYCHOSOCIAL MODEL

The biopsychosocial model requires that biological, psychological, and causal factors causally interact with each other. Hitherto this has been hard to theorize, but the current life and behavioral

sciences show how within- and cross-domain causation works. The biopsychosocial model is a model for medicine proposed by the physician and psychoanalyst George Engel at Rochester, New York, in a series of papers in the late 1970s and early 1980s. The main contrast is with the biomedical model, which focuses on biological factors in disease, while the proposed extension broadens the scope to include psychosocial as well as biological factors. The biopsychosocial model and its comparisons and contrasts with the biomedical model raises many questions for theory across the range of the relevant sciences: the life sciences, the behavioral sciences, and the social sciences, as well as the environmental sciences.

Medicine is an applied science making extensive use of technology for detection and treatment, of many kinds, ranging from physics-based technologies to psychosocial. The biopsychosocial model can also be used as a frame for health professional–patient relationships, emphasizing the importance of taking account of the person as a whole. Although primarily a model for medicine, the biopsychosocial model arose at the time of revolutionary changes in the life and behavioral sciences. Centuries-old assumptions about physical nature, mind, and causation were being overturned, being replaced by foundational concepts such as information processing and systems science. A consequence of these changes is that what was hitherto a disunity among the sciences has given way to increasing recognition of the need for cross-disciplinary research programs.

Biomedical and Biopsychosocial Models

The Basic Contrast

Biomedicine is a set of basic biological and clinical science research programs with associated technologies for detection and treatments. It has made great advances in the understanding of many diseases and in the treatment of many, most spectacularly for infectious diseases, but many others besides. The core basic science is physiology,

increasingly enhanced by advances in the understanding of basic cellular processes and genetics. For practical purposes, biomedicine hardly needs a general model, but it does have the working, methodological assumption that diseases can be understood only or primarily in terms of biological factors. This assumption can be called the *biomedical model*. In 1977, George Engel proposed a new model for medicine, the *biopsychosocial model*, arguing that the biomedical model was too narrow in its focus on biological factors, and that, rather, medicine needed to take account of the full range of biological, psychological, and social factors.

Multiple Issues Involved: Etiology, Treatment, Boundaries

The issues involved in the biopsychosocial model are large, abstract, and complex. The broad question whether psychological and social factors as well as biological factors are involved in health and disease arises in many contexts: the etiology of disease, course of disease post-onset, complications by further health problems, and treatments. In addition, there is the question of how we draw the boundaries between what is disease and what is within the normal range of variation. In each of these cases the question arises, Are the main factors and considerations biological, or are they rather broader, biopsychosocial? All of these issues are of major importance in the health sciences and health care, and they are all in play in Engel's papers proposing the biopsychosocial model. This gives rise to significant ambiguity as to exactly what is being proposed, which is likely one reason for the model's mixed reception, as discussed in what follows.

Deep Theory Also Involved: The Nature of and Relation between Biological, Psychological, and Social Factors

Further, Engel's papers penetrate into deep theoretical issues, including whether biology is reducible to physics and chemistry; the need to abandon the dualism of mind and body; and the importance of causal interactions between biological,

psychological, and social factors. These theoretical issues will be taken up later in this entry.

Mixed Reception of the Biopsychosocial Model

Widespread Acceptance

It would be reasonable to say that the biopsychosocial model is the dominant headline model of the contemporary practice of health care. It is endorsed as obvious by many health scientists, clinicians, and health educators, and as especially important for quality of clinical care and health care education. It is obvious enough that the patient as a whole has a biology and psychology and social life, and that this is important to bear in mind when treating.

Radical Criticisms of the Biopsychosocial Model

Alongside widespread assent to the biopsychosocial model, however, amid its apparent obviousness, another theme in the reception of the biopsychosocial model is that it is vague and useless. The criticism is that the model is mere hand-waving, that it makes no specific scientific claims and gives no specific clinical guidance but can be used to justify anything or nothing. Thus, we have the intriguing picture as a whole that the biopsychosocial model is widely endorsed, but at the same time criticized for being too general and vague to be of any use.

Maybe the Biomedical Model Is Enough?

In the meantime, biomedicine continues to make substantial advances in the treatment of many diseases and continues to attract a high proportion of health research and clinical funding. At the time of writing, Fall 2020, promising interim results of the first to report Phase 3 trial of a vaccine for COVID-19 have just been released; the latest example of great success for biomedicine. More generally, the two most rapidly expanding basic health care sciences, genetics and neuroscience, both appear to be biological, insofar as they focus on biological factors—issues picked up in

the last section. In the context of the continuing success of biomedicine, it can be readily acknowledged as obvious that the person as a patient has a psychological and social life as well as a biological body, and that this has to be kept in mind when managing an illness, while noting that this can be so even if the core disease process is primarily biological, requiring a biological intervention.

The Need for Evidence

Following the preceding line of thought, the biopsychosocial model only presents as a genuine alternative to, actually as an extension of, the biomedical model, inasmuch as it can be shown that psychosocial factors as well as biological factors are causally relevant to the onset and course of diseases. Such evidence has been gradually accumulating over recent decades as reviewed in the following section.

Evidence Base

New Group Research Methodology

The biopsychosocial model was proposed at a time, the late 1970s and early 1980s, when there still tended to be competing theories about the nature of illness in general—that it was caused by one or other of biological, psychological, or social factors. Research was confined mainly to case studies. It was not until the closing decades of the 20th century that randomized controlled treatment trials came into widespread use. Treatment trials are in a class of controlled research designs and associated statistical analytical modeling capable of estimating the proportion of variance in a health outcome of interest attributable to particular factors. The same approach has been applied in epidemiology to investigate risks for development of disease. These new research methodologies have been used to study empirically and quantifiably the role of biological, social, and psychological factors in the onset and treatment of diseases.

Evidence Base for Psychosocial Factors

Findings in epidemiology over the past few decades have included identifying the so-called social determinants of health. The novel finding

has been that social disadvantages are implicated in the onset of many kinds of health problems, physical and mental. There are also many clinical trials showing the importance of psychological treatments in affecting (a) the course of mental health conditions and (b) the adjustment and mental health complications of long-term physical health conditions.

Evidence Base Is Typically Condition- and Stage-Specific (Not “General”)

As these findings have accumulated, they have lent clear support to the biopsychosocial model. That said, the research evidence is specific rather than general; it distinguishes between conditions and stages of condition. In advanced stages of some physical illnesses, such as Ebola virus disease, or Grade 4 cancers, or advanced cardiovascular disease, the driving processes are typically biological only, and treatments, if there are any, are accordingly biomedical. On the other hand, if one looks for risks of disease, whether they be lack of environmental hygiene, or unhealthy diet, or chronic stress associated with economic disadvantage, the causal factors broaden out into biopsychosocial. This broader picture also applies to adjustment and quality of life in chronic health conditions. There is no biomedical cure for long-term conditions, though biomedical management may be critical, and questions of lifestyle and quality-of-life implicating psychological and psychosocial factors come to the fore.

Practical Implications of the Biopsychosocial Model

Public Health

The new findings in social epidemiology imply that reduction in population prevalence of disease would require policy to address chronic stress, with its associated biological damage, by alleviating socioeconomic disadvantages. Public health in this new context is closely linked to economic policy, and generally to policy to alleviate social exclusion from health-related resources such as clean air, healthy diet, and a living wage. Psychosocial factors are also increasingly emphasized in public health strategies to manage infectious disease epidemics, such as population cooperation

with infection control measures and high-enough vaccine uptake.

Clinical Treatments

Treatment trials for many health conditions have suggested efficacy of a range of psychosocial treatments. Such findings lend support to the biopsychosocial model. However, the biopsychosocial model is general and is no substitute for the detailed findings of treatment trials. We now have systematic reviews of treatment trials that summarize the findings for a particular condition or for a particular stage of a particular condition. These reviews discriminate between the scientific quality of the trials and make recommendations as to management and treatment. These recommendations, or treatment guidelines, always come with the qualification that each patient and presentation is unique, having a unique combination of factors that cannot all be taken into account when inferring an individual management plan from a range of group treatment studies; and that, accordingly, individual clinical judgment in deciding a clinical management plan is required. Treatment plans may be biological, psychological, or social (as in so-called social prescribing), alone or in some combination, typically requiring a multi-skilled, multidisciplinary team. Good clinical care of the patient always involves respecting the whole person.

Theorizing Biological, Psychological, and Social Factors

Dualism and the Reduction

Problem: Material Causes Only

At the theoretical core of the issues considered so far are the questions of what biological, psychological, and social factors are, and how, if at all, they interact. The life and human sciences have developed over the past or so against the background of mind/matter dualism that created deep theory prejudices: that nature consisted of physical matter and physical causes alone, and mind, the realm of cognition, was either noncausal or in some way identical to the material brain and behavior. As to social reality and causes, in this picture they are hardly conceivable. In the 1970s, it was commonly and still reasonably believed that biology was

reducible to physics and chemistry. The stunning successes of biomedicine in identifying the biological causes of many diseases thus coincided with the deep theoretical or philosophical assumption that anyway all causation had to be biological, ultimately a matter of physics and chemistry. Engel proposed the biopsychosocial model in the 1970s against the background of the deeply antithetical assumptions that psychological and social causes were highly problematic ideas, whereas biological causation alone seemed legitimate. The proposal, however, was a signal of what was to come; around the very same time interrelated revolutions in biology and psychology were in the process of undoing the traditional assumptions.

What Is Biology? A New Science of Regulatory Control

A key theory contribution to revolutionizing biology was made by the physicist Ernst Schrödinger, famous for his work in quantum mechanics, in a lecture delivered in Dublin in 1943, in which he proposed that life could be understood as a local system in which the overall direction of the second law of thermodynamics ran, temporarily, in reverse: in biological systems, entropy is decreased; order, energy differences, increased. Schrödinger saw further that this extraordinary feat was accomplished by genetic coding—a new concept that remained to be worked out. Ten years later Watson and Crick published their work on the structure of DNA and the genetic code. From around that time, biology, physiology, including biomedicine, has developed as a balanced combination of two sciences: the biophysics and biochemistry of energy exchanges, for example underlying basic cellular metabolism, but this combined with a new science of regulatory control of those processes based on information exchange or communication. Current biomedicine is in large part a study of regulatory mechanisms regulating metabolic processes and other regulatory mechanisms. This new science has logical formulae for its mathematical representation: regulatory mechanisms are basically stop/start, represented by negation, and dependent on conditions, represented by “if . . . , then. . . .” Information processing science interweaves with computing.

The new framework of causal explanation in biology in terms of information- or communication-based regulatory control is also applicable in the behavioral and social sciences. This enables a more unified science in which there can be causal interactions between these previously disparate domains.

The Psychological as Embodied Agency and the Social as Resource

The new information-processing paradigm also revolutionized psychology at around the same time, in the so-called cognitive revolution in psychology. While early computational models of mind in the 1970s were computerlike, emphasizing only manipulation of symbols, increasingly, as the research program has evolved, the mind is seen as more biological, embodied, in close interaction with the environment. These theories of embodied cognition were first recognized in the tradition of philosophical phenomenology but are now at the cutting-edge of neuroscience. Important for the purpose of unifying the science, and implied by the common use of the information-processing paradigm, there are information-based regulatory pathways between the mind–brain and some biological systems below the neck, linking neuroscience with biomedicine. The mind–brain also regulates behavior in the environment; accordingly, agency as the capacity to act is an overriding function. Regulation is a core feature of social causes, as well as of biological and psychological causes. The environment for us includes the whole range of factors—physical, chemical, biological, and social—and our biological and psychological functioning depends on it. The biopsychosocial model needs to include the environmental sciences.

Causal Interactions

The core consequence of these theory shifts in the basic sciences are that causal interactions are possible between what were previously disparate domains, which now become linked in a unified ontological–causal space. A sign of this in health sciences are multifactorial models of causal

interaction, such as between genes, lifestyle, and environmental exposure, in pathways to many health conditions. This development in the health sciences is part of a broader recognition of the need for problem-solving research programs to be multidisciplinary.

BIOSTATISTICS

Biostatistics is both a practice and a profession. As a practice, it involves addressing biological or medically related themes using quantitative reasoning. As a profession, biostatistics can be understood as a different type of practice, one that is widely institutionalized, primarily in North America and Europe, with its own societies, associations, journals, commonly taken-for-granted skills and credentials, and applications. After describing this basic terminology, this entry provides context for both the practice and profession of biostatistics as a series of three historical epochs: (1) its *gestation phase*, which largely began in the 19th-century Europe and the United States; (2) its *foundation phase*, whereby in the early 20th century, renewed debate over the nature of evolution led to one of the most historic accomplishments in science: the consensus across a broad array of disciplines in the process of Darwinian natural selection; (3) its *institutionalization phase*, in which the practice and profession of biostatistics became more widely institutionalized, particularly in the United States, along with a larger process of societal medicalization. The entry concludes with a discussion of some of the promises and perils for biostatistics in the 21st century.

Terminology: The Duality of Biostatistics

This section makes two main points. First, that the term *biostatistics* is semantically vacuous: most definitions of biostatistics have either been terse and limited to a one-sentence description, or definitions of biostatistics have been stretched to a dizzying array of domains. To clarify the first point: Biostatistics encompasses a wide variety of statistical applications to biological phenomena. Beyond this statement, further clarification is warranted.

Second, I claim that understanding biostatistics can be clarified further by distinguishing biostatistics as a practice, or *what some people do*

and biostatistics as a profession, or *what some people are*. In other words, biostatistics as a concept can be purposefully widened beyond the tight definitional circularity in which it presently finds itself.

What Is Biostatistics?

The term *biostatistics* is vacuous because, as a concept, it is too broad to be very meaningful. Its sacrificial breadth is not unreasonable to compare it to Jorge Luis Borges's famous short story about a map that was made to such exacting detail that it became as large as the empire it was intended to represent. This *map-territory* problem is a conceptual problem in clarifying the concept of biostatistics: as a construct, it is too encompassing to be very meaningful without being circular semantically. The concatenation of "bio" with "statistics" is most accurately described as a "shotgun wedding at best" (by Morgan, 1986, p. 1105), primarily because it does little to clarify in specific terms or in specific contexts the practice of biostatistics. To define biostatistics as the application of statistics to biological phenomena does not clarify much if the reader knows the word root *bios* is Greek for *life* and that the word *statistics* refers broadly to the classification, collection, analysis, and inference of numerical facts or data. Several exchangeable terms predate the term *biostatistics*. For example, the first recorded use of the term *biostatistics* in the third edition of a dictionary of "medical lexicon," by notable English and American physician Robley Dunglison, refers the reader to the earlier term *medical statistics*, which was used in the volume's 1842 second edition (1865, pp. 138, 654). Even before the concept of biostatistics there were a plethora of other concepts that were used interchangeably with the term *biostatistics*, but which mean different things, including *biostatics*, *biometry*, *biometrics*, *biological statistics*, *medical statistics*, *biostatistical science*, and *biomedical sciences*. More recent terms include *environmental statistics*, *pharmaceutical statistics*, and *public health statistics*.

The Practice/Profession Distinction

To clarify the concept of biostatistics, we need to distinguish between the term as referring to a *practice* and as referring to a *profession*. To preview, biostatistics as a practice emphasizes what is meant when one *does biostatistics*, such as how a question is framed, what topic is addressed, and the procedure or method employed. In contrast, biostatistics as a profession focuses on how people *be biostatisticians*; that is, on how biostatistics has developed as discipline with its own societies, journals, and its own linkages with governmental institutions.

Biostatistics as a practice is relatively ambiguous; however, intuitively, the word itself references both the *statistics* (*statistics* broadly speaking, but more fundamentally a positivist approach toward knowledge construction) and *biology* (*bio*, referring to anything biological). The practice of biostatistics has varied over time and space in its application. About the only unifying methodological approach is its emphasis on quantification. While the practice of biostatistics is difficult to define, greater traction is possible by viewing it as a profession. In this context, professionalization refers to the social processes by which an occupation or a particular status is symbolically and socially constructed.

Beyond these two categories, biostatistics may refer to any number of data analytic techniques and may include any number of applications. The following are only a few topical examples, such as: the study of population prevalence of births and deaths (calculation of so-called *vital statistics*), the study of population health (*epidemiology*), the distributions and changes of genetic diversity of a population (*population genetics*), the sequence of *genomes* or genetic material of an organism or organisms (*bioinformatics*), the study of drug action (*pharmacology*), not to mention applications in agriculture, ecology, animal studies, health economics, and botany, among many other fields. The best way to understand biostatistics is to likely paraphrase famous statistician John Tukey's line: While statisticians "get to play in everyone's backyard," biostatisticians get to play in everyone's "garden," focusing not on the space as a play area, but rather on its flora and fauna.

Another point to be made is that, in large part because of the field's influence on statistics in general, while there are some statistical applications more commonly applied in biostatistics, such as sequence analysis, the majority of biostatistical methods could apply to almost any discipline, although the terminology may differ. For example, while biostatisticians refer to as *hazard* or *survival analysis* as a technique to understand the timing of an outcome (such as "number of years lived before death"), this same technique is sometimes referred to in economics as *duration analysis* and in history and sociology as *event history analysis*.

It is perhaps not surprising that most biostatisticians focus primarily on methods and on data applications. For example, in Wayne Daniel's accessible (and recommended) introduction, *Biostatistics: A Foundation for the Health Sciences*, nearly all of the textbook focuses exclusively on statistical applications, using examples in the health sciences, but with only a brief definition of the term on the third page. Accordingly, the major specialty journals such as *Biometrika*, *Biostatistics*, *Statistics in Medicine*, and *Pharmaceutical Statistics* tend to address new methodological innovations and findings from particular analyses, avoiding the ontological trap of attempting to define the subfield.

The Genealogy of Biostatistics in Three Acts

This section traces the *genealogy* (to borrow Michel Foucault's term) of biostatistics to understand its present incarnation as a historically situated phenomenon. By sticking to historical facts, one can begin to understand biostatistics *not* as I conceitfully introduced it—as a term so vacuous as to embody everything—but rather to understand its *specificity*.

Although biostatisticians are apt to identify pre-19th century, canonical figures, it is important to consider that biostatistics codeveloped with science more broadly and statistics and biology in particular. Biostatistics is best understood as a 19th-century phenomenon, closely aligned with progressivism and with eugenics in the early 20th century, but primarily an established discipline in

the post–World War II period in the United States. As a practice and as a profession, biostatistics has made great contributions to statistics, science, as well as population health. While biostatistics as a practice will undoubtedly continue, there are important questions regarding the future of the profession, in part due the inchoate boundaries of the discipline combined with rapid advancements in technology.

Gestation (1800–1900)

First, and perhaps most importantly, there was the rise of the bureaucratic nation-state, which created an avalanche of printed numbers that required bureaucratic thinkers to both consolidate and manage each state's *informational capital*. By the early 19th century, France, Germany, and the United Kingdom created governmental bodies devoted to collecting statistics on their citizens. A notable example in the United Kingdom was the transition from the church of vital records (e.g., births, deaths, marriages) to the government. In particular, in 1836, the United Kingdom established the General Register Office to manage to supply all vital records and assigned physician William Farr to manage the records. A centralized governmental agency took over the role of the Church of England in large part because of the increasing number of nonparticipants and Catholics in the United Kingdom.

Second, in large part because of the rise of the nation-state, European scientists and philosophers began rejecting the philosophy of causal determinism in favor of a theory of probabilistic thinking that provided an understanding of the world that made it seem less disorderly. Causal determinism was the view that the universe is established mechanistically, with every event occurring in a lawlike fashion in a predetermined causal chain of events. In contrast, probabilistic thinking provided thinkers to develop knowledge that focused on variation among populations and to think of social problems in terms of chance or risk. Bureaucrats armed with an *avalanche of numbers* used such resources to generate a philosophy of chance that guides much of statistical thinking today.

Third, the 19th century underwent political and social movements that promulgated *progressivism*, a broad philosophical idea that asserts that human advancement is made possible through technological economic development in conjunction with the practical application of scientific principles. Progressivism has its roots in 17th-century European Enlightenment ideals emphasizing reason, individualism over tradition, and with such famous French and English thinkers as Francis Bacon, John Locke, Voltaire, David Hume, and Isaac Newton. Although a review of such a grand concept is beyond the scope of this analysis, it is important to underscore that early thinkers were largely (and in many respects) are at least implicitly influenced by this moral worldview. Early 19th-century researchers such as John Snow, who provided evidence regarding the spread of cholera, sought to apply statistics in the service of social good; that is, of addressing the problems that came alongside the industrial revolution, particularly the spread of disease.

The fourth branch of influence can be traced to Charles Darwin's theory of natural selection, which he famously published in *Origin of the Species* in 1859. Despite Darwin's huge influence in biostatistics, it is important to note that biological applications of statistics had occurred previously for centuries, first as the Catholic Church documented births and deaths in its *registry of souls* and then in the early 19th century, particularly as British bureaucrats sought to determine the *quantum of sickness* through cataloging human existence in *life tables*.

Nevertheless, the late 19th and early 20th centuries underwent a series of social movements focused on manipulating population genetics for the betterment of humanity. This fourth branch can be traced to the ideas of Francis Galton, the developer of one of the first surveys and the creator of *regression* models, who also coined the term *eugenics*, combining the Greek roots for *good* and *genes* or *born*, based on the ideology that improving the genetic composition of society requires both the application of rational thinking and progressive ideas toward understanding and manipulating human population genetics.

In summary, it was a combination of events in the 19th century, predominantly resulting from the *avalanche of numbers* created in the early 19th century, combined with new social problems in during the industrialization of Europe, that led to changes in the way great minds thought about causality and about the role of science. These seeds gestated into what can be called the *golden era* of biostatistics, as it rose to great prominence in human society.

Foundation: 1901–1946

The foundation phase of biostatistics is marked by one of the most remarkable achievements in Western civilization: the adoption across a broad range of disciplines of Darwin's gradualist theory of natural selection. The early 20th-century contributions of members of the *Biometric school* helped resolve a decades-long debate regarding the process of evolution (i.e., whether it is gradual or characterized by a series of *jumps*). The debate was reignited in 1900 with the rediscovery of Gregor Mendel's pea plant experiments. Using quantitative evidence, scientists demonstrated that fundamental questions touching on religion and philosophy, in addition to biology, could be answered scientifically. By the 1940s, scientists reached consensus that Darwin's theory of evolution as a slow, gradual process was empirically valid. This *modern evolutionary synthesis*, as it has been famously called, underscored to both scientists and to the lay public the great possibilities with biostatistics.

The foundation of biostatistics cannot be appreciated without recognition of the discipline's trailblazers in the early 20th century. Members of the Biometric school such as Karl Pearson, R. A. Fisher, and W. F. Weldon achieved fame for viewing evolutionary debate as largely a *statistical problem*, as Weldon put it, and by developing foundations of modern statistical analyses. For example, Fisher developed the *analysis of variance*, the method of *maximum likelihood*, and Pearson developed the eponymous *R correlation coefficient* widely used today. Together, they developed standards for assessing statistical significance and the concept of a *Type I Error* (a false detection of a statistically significant result). The growing methodological development of statistics

as applied to biological questions was marked by the establishment by Fisher of the journal *Biometrika* in 1901.

In addition to the remarkable achievements of the founders of biostatistics, it is important to underscore that they also viewed their developments within the political project of progressivism and of eugenics. Accordingly, Fisher participated in several eugenics societies and published his research in the journal *Eugenics Review*. Largely influenced by Darwin's theory of evolution, eugenicists sought to improve population health; not surprisingly, these ideas transmigrated to Europe, where they were carried into action by the Nazis. After World War II, eugenics as a social movement largely collapsed. Nevertheless, the rise of biostatistics, particularly in American society, maintains at least an implicit Progressivist approach toward societal health, leaving behind eugenics ideology.

Despite the early association of biostatistics with political controversy, its utility as a practice far outweighed any controversy; it is important to note that statistical methods were also developed during World War II, even if these did not have biological applications. Later biostatisticians would build upon the theories developed by Fisher and Pearson, focusing on broader progressive ideals addressing public health more generally.

Institutionalization: 1947 to the Present

Biostatistics did not become its own professionalized field until the mid-20th century. For example, biostatistics first became an independent discipline recognized by the National Institutes of Health in 1946 alongside the establishment of the Center for Disease Control. Professional societies for biostatistics also lagged behind those of statistics. For example, the American Statistical Association was established in 1839, and in England the Royal Statistical Society was established in 1834. The International Biometric Society, however, was not established until 1947, and the Biometrics Section of the American Statistical Association was not adopted until 1950. Other leading journals such as *Statistics in Medicine* were not established until much later, in 1982.

One way of understanding the development and professionalization of biostatistics in the post-war United States is to understand biostatistics

within the *medicalization of society* in the United States more broadly. The term *medicalization*, typically used by sociologists at least since the 1970s, refers to the increasing use of medical language and diagnoses to understand social phenomena. As the 20th century progressed, biostatisticians increasingly influenced the practice of care, as medical professionals used statistics to make important decisions regarding social policy and diagnoses.

A number of advancements occurred within the postwar period, building primarily from the early work of founders. First, physicians and statisticians worked in unison to define and to understand population prevalence of health risks with the development of large-scale surveys. New methods such as survival models were developed to assess mortality and other health risks. Second, with the aid of institutions such as the National Institutes of Health, biostatisticians began developing formal clinical trials to test the efficacy and safety of drugs and other health interventions, largely influenced by R. A. Fisher's theories regarding randomization, but also influenced by the notable statistician and epidemiologist Sir Austin Bradford Hill, who established a set of criteria (the so-called Bradford Hill criteria) for assessing causality in randomized-controlled trials.

In more recent decades, as sociologist Peter Conrad points out, *medicalization* has become increasingly privatized, with biotechnological revolutions, the rise of large pharmaceutical industries, and the rise of managed care. In contemporary Europe and the United States, biostatisticians are increasingly working in commercial fields rather than in academic domains, as private entities rely on biostatistical knowledge to define and simultaneously treat medical problems.

As higher education expanded in the United States and beyond, biostatistics departments began to develop in the postwar era, producing specific credential programs. Nevertheless, the disciplinary boundaries of biostatistics within the academy are still porous at best: the field is often subsumed under statistics departments or amalgamated within schools of medicine, public health, or epidemiology. Nevertheless, increasing numbers of advanced degrees in biostatistics are offered in major universities around the world, almost all of which are postgraduate degrees.

Conclusion: Are We All Biostatisticians Now?

This entry has distinguished biostatistics as a practice and as a profession. As a practice, biostatistics involves the marriage of quantitative methods to biological subject matter. As a profession, biostatistics has grown enormously over the 20th century and thereafter, and, like any profession, has its own institutions, educational credentials, professional groups and societies, and specialty journals. There are two new dynamics that affect the future of biostatistics. In what follows, we will revisit the practice/profession distinction and assess the implications of the big data revolution, so-called, on the behavioral, ecological, educational, and social dimensions of biostatistics.

The *big data revolution* is a term coined in recent years to refer to four aspects of quantitative data analysis. First, owing to increases in computing power, the digitization of records, and the incorporation of technology into everyday social life, there is greater availability of data than has ever been produced before in human history. Second, statistical software is increasingly accessible, with the availability of free, user-generated programs such as R or Python, the increased efficiency of computing power to produce faster results, and the greater availability of more user-friendly interfaces. Third, the big data revolution has led to the availability of online learning sources that have made esoteric statistical knowledge more accessible both within and outside the academy. Fourth, there is a recent cultural revolution: motivation to learn statistics has exploded, as statistical applications have found their way into every aspect of social and professional life. In short, technological advancements have made data more available, analyses easier to implement, skills more accessible, and motivation more widespread.

These implications are both positive and negative for biostatistics. From a practice perspective, biostatistics may far surpass the *golden age* of the 20th century. Soon, nearly everyone may become a biostatistician. From a professional orientation, however, biostatistics may be difficult to maintain as an exclusive profession as more nonprofessionals make substantial contributions to the field. Another concern iterated in biostatistical journals

is ensuring *good* statistical standards in light of greater numbers of participants.

Notwithstanding, if professionalism is the primary bulwark against expanding the contributions of biostatistics, one should be reminded of the pioneers *avant la lettre* who made major contributions even as amateurs. Take for example, John Graunt, often cited in biostatistics as a founding figure, who used public records in an attempt to quell the spread of bubonic plague in 17th-century London. Along the way, he was the first to calculate the population of the city and has been called the *father of demography*. Graunt was, however, a haberdasher by trade. How many future John Graunts are there today, working to contribute to our collective knowledge of the world around us?

CATEGORY THEORY

Categories were first introduced by Samuel Eilenberg and Saunders Mac Lane in a paper entitled “General Theory of Natural Equivalences,” published in 1945. A term dating from that time, *general abstract nonsense*, refers to its high level of abstraction compared to classical branches of mathematics. Category theory looks at mathematics on a large scale, examining objects and the relations between them in the abstract, with the aim of stripping away inessential details to get to the essence of things.

This entry provides a brief overview of the history of category theory, and some illustrations of the utility that mathematicians have found in it. It is interesting as an example of how a transformation in how one thinks about the nature of theories at a very high level of abstraction in some discipline can have important implications for how theories are structured and used in that discipline.

Just as objects tend to blur together when we screw up our eyes, category theory allows us to see the underlying similarity between objects previously considered quite different. It provides a way to explore the relationship between different kinds of mathematical objects, for example, products and functions, and abstract from unnecessary details to obtain general definitions and results. It focuses on how things behave, rather on what their internal details are. Category theory is a powerful tool for both philosophers and logicians.

Category theory works from the outside to infer general laws of algebra. An object in category theory is a complete algebra, like a *black box* where we cannot see directly inside and can only know its external properties. We cannot make arbitrary choices about what may be inside an object, we can only describe it as an *isomorphism*. For example, in set theory we think of sets as defined by their members, and we consider functions mapping one set to another in terms of those objects. Category theory, by contrast, treats the mappings between categorical objects directly and does not consider the nature of the internal elements.

However, we can still learn a lot about a category in this way, by investigating how high-level rules, like the axiom of association, are implemented and how identity (e) functions in the category. By doing this in a very general way, we can apply what we learn about one category to other categories.

Much of modern mathematics, from algebraic geometry and homological algebra to logic and topology cannot be imagined without the organizing principles of category theory. It allows us to perform proofs in a purely equational or diagrammatic style of reasoning. It is useful in computing because algebraic structure naturally arises in many different areas of computing, including formal semantics, language design, programming logic, type systems, and programming calculi. Many divisions of the sciences (physics in particular) are discovering categorical ways of thinking to be useful.

History of Category Theory

Category was a term used in Aristotelian mathematics, much later redefined for the purpose of category theory. Categories, functors, and natural transformations were terms first introduced in 1945 when Eilenberg and Mac Lane published a paper titled “The General Theory of Natural Equivalences.”

In 1956, Henri Cartan and Eilenberg published “Homological Algebra,” which enabled mathematicians to learn about algebraic topology and homological algebra in the new categorical language and to understand the new types of diagrams.

In 1957, the German-born French mathematician Alexander Grothendieck published a landmark paper “*Sur quelques points d’algebre homologique*” (“On some points of homologic algebra”) where categories were used intrinsically to define and construct more general theories including algebraic geometry. By using the axiomatic method and language of categories, Grothendieck formulated an abstract type of categories.

In 1958, Daniel M. Kan illustrated that adjoint functors can capture basic concepts in other areas including homotopy theory. Later, category theorists Peter Freyd and Bill Lawvere came to understand that the existence of adjoints to given functors allows there to be definitions of abstract categories.

By the early 1970s, the concept of adjoint functors was a central one to category theory. Category theory became an autonomous area of research, and pure category theory was developed. The theory grew quickly both as a discipline and in terms of its applications to algebraic topology, homological algebra, and algebraic geometry. Lawvere proposed the *theory of categories* for set theory, and thus the entire realm of mathematics, and used categories for the study of logical aspects of mathematics. He axiomatized the category of sets, gave a categorical description of theories independent of syntactical choices, and argued that functors should play a foundational role in category theory.

Present-day category theory is used in theoretical computer science, mathematical physics, and has contributed to the development of new logical systems.

Categories, Objects, and Morphisms

In everyday speech, we think of a category as a kind of thing. A category consists of a collection of things all of which are related in some way. In mathematics, a category can also be looked at as a collection of *things*, and a type of relationship between pairs of such things.

To count a duo of things as a category we need to adhere to two rules: That every *thing* be related to itself by simply being itself, and if one thing is related to another and the second is related to a third, then the first is related to the third. In a category, *things* are called *objects* or *sets*, and the relationships or typed total functions are called *morphisms*.

Morphisms are the mappings that preserve the structures between objects. By examining these morphisms and the way they compose or their paths commute, we can understand more about the object’s structure.

Relations between morphisms are often depicted in commutative diagrams with *points* or corners, representing objects and *arrows* representing morphisms. By studying the arrows, we can look at properties of spaces that do not involve drawing complicated pictures in higher dimensions, since the space is represented by a single point and arrows are one-dimensional.

For example,

The existence of an identity arrow for each object and being able to compose the arrows associatively are basic properties of a category. A simple example is the category of sets, where the objects are sets and the arrows are functions.

However, the objects of a category do not have to be sets and the arrows do not need to be functions; any method of formulating a mathematical concept to meet the basic conditions of the object’s and arrows’ behavior is a valid category, so that category theory will apply to it.

Categories are considered identical if they have the same collection of objects and arrows and use the same associative method to align pairs of arrows.

The class $\mathbf{Grp}$ of groups consists of all objects having a *group structure*. We can prove theorems about groups by making logical deductions from sets of axioms. For example, we can immediately prove from the set of axioms that the group's identity element is unique.

When discussing groups, these morphisms are termed *homomorphisms*. A group homomorphism between two groups *maintains the group structure* precisely—it is a method of taking one group to another, so that information about the structure of the first group gets carried to the second group. The study of group homomorphisms then provides a tool for studying general properties of groups and consequences of the group axioms.

Well-known categories are denoted by a shortened capitalized word or abbreviations in bold or italics: examples are **Sets**, the category of sets and set functions; **Rings**, the category of rings and ring homomorphisms; and **Tops**, the category of topological spaces and continuous maps. All the former categories use the identity map as an identity arrow and composition as the associative process on the arrows.

Functors

A category is a type of mathematical structure, so we can look for processes that preserve this structure. This process is known as a *functor*. Functors are represented by arrows between categories. They can define categorical diagrams and sequences and associate to every object of a category an object of another category and to every morphism in the first category a morphism in the second.

Objects are categories, and morphisms between categories are functors. By studying categories and functors, we are not simply studying a class of mathematical structures and the morphisms between them, we are studying the relationship *between various classes of mathematical structures*. Difficult topological questions can be translated into algebraic questions which make solving them easier. Basic constructions, for example, the fundamental group or fundamental groupoid of a topological space, can be expressed as fundamental functors to the category of groupoids in this way, and the concept is pervasive in algebra and its applications.

Natural Transformations

Saunders Mac Lane, one of the founders of category theory, stated that his objective was not to study functors but to study natural transformations. Without a study of functors, the study of categories would not be complete. But the study of functors could not be complete without the study of natural transformations. This needs to be put in the context of the axiomatic theory of *homology*. Homology in algebraic topology and abstract algebra is a way to associate a sequence of abelian groups within a given mathematical object, for example, a topological space or group.

Some diagrammatic and some sequential constructions can be *naturally related*—which can at first glance seem vague. This leads us to the clarifying concept of natural transformation, which is a way to map one functor to another. This has led to a context in which many important mathematical constructions can be studied. *Naturality* is a principle in physics that is more significant than it first appears. An arrow or morphism between two functors is called a *natural transformation* when certain conditions such as naturality or commutativity apply to it.

Functors and transformations are the key concepts in category theory. A natural transformation can transform one functor into another while maintaining its internal structure that is the composition of morphisms in the category. A natural transformation is essentially a morphism of functors, an intuition that can be used to define functor categories. Natural transformations are fundamental to category theory and are evident in most of its applications. Natural transformations are categorical in nature, so particular maps between functors are consistent throughout a category.

A particular map between individual objects, rather than entire categories, is termed a *natural isomorphism*. This means that it is defined on the whole category and defines a natural transformation of functors. There is also such a thing as an *unnatural isomorphism*, which is created if a category-wide map cannot be extended to a natural transformation.

Equivalence

Equivalence is a relationship between two objects in a similar way to equality and isomorphism but

is weaker and more general. Isomorphism is weaker than equality and equivalence is weaker still. If we take two mathematical objects, A and B, to be compared and we construct two morphisms between them, C and D, then E and F must be selected so that by applying them (composing them) we get back to the isomorphic from whence we started.

Category theory is a broad topic and has the potential to be applied across many branches of mathematics. From a philosophical point of view, category theory provides a challenge to philosophers to tackle the general, ontological, and epistemological status of categories and categorical methods.

CELL THEORY

The cell is the basic unit of organization or structure of living matter. All animals and plants are composed of cells and cell products; all tissues and organs are composed of cells. Among the various landmark biological theories formulated in the 19th century, cell theory was to become a great unifying concept and one of the key principles of biology. Indeed, in explaining the

organization of living systems, cell theory provides the foundation for understanding the growth and reproduction of organisms. No matter how big or small, or how simple or complex they might be. This entry takes a close look at the components and characteristics of cells, plant, and animal, as defined by cell theory and its close relative, biogenesis theory.

Origins and Basic Principles

It was the invention and refinement of the microscope by Dutch lens makers Hans and Zacharias Janssen in the 17th century and subsequent observations of tiny specimens by the Englishman Robert Hooke and the Dutch self-taught scientist Anton van Leeuwenhoek—who was the first to observe bacteria and other single-celled organisms—that eventually gave rise to cell theory and its cousin, biogenesis theory. Cell theory, first proposed in the late 1830s by two German scientists, Matthias Jakob Schleiden (a botanist) and Theodor Schwann (a zoologist), posits that—as affirmed by more than a century of published reports by trained observers—all living things are composed of cells. Biogenesis theory, proposed in 1858 by the German physician, historian, and pathologist Rudolf Virchow, states that all living cells arise from existing (living) cells, and that no cells are created spontaneously from nonliving matter. Classical cell theory, as developed through the observations of Hooke, Leeuwenhoek, Schleiden, Schwann, Virchow, and others as a fundamental theory in biology, includes the following three principles:

1. All organisms (animals, plants, and microbes) are composed of one or more cells.
2. The cell is the smallest unit having the properties of life, the basic unit of organization of living organisms (i.e., the cell is the basic unit of life).
3. All cells come from preexisting cells; that is, no cell can originate spontaneously but comes into being only by division and duplication of already existing cells.

These basic principles or ideas still hold true and they provide the foundation for everything that modern researchers have learned about cells.

Cell theory has had wide biological applications. With the progress of biochemistry, it was shown that there were fundamental similarities in the chemical composition and metabolic activities of all cells.

Discoveries That Led to Cell Theory

As noted earlier in this section, cell theory was developed from three German scientists' discoveries. They are Matthias Schleiden, Theodor Schwann, and Rudolph Virchow. In 1838, Schleiden discovered that all plant tissues he observed under the microscope were composed of cells. Then only a year later (1839), Schwann discovered that all animal tissues he observed in similar fashion were composed of cells. Later, in 1855, a Virchow was doing experiments with diseases when he found that all cells come from other existing cells. Cells of course were discovered much earlier. The first person to see a cell was the English scientist Robert Hooke (1635–1703). He used a very primitive microscope, but when he was using it to examine a thin slice of cork, he saw cells for the first time. Their shape reminded him of monks' cells in monasteries and so he dubbed them cells. As mentioned above, the first person to see living cells was Anton Van Leeuwenhoek, a Dutch microscope builder.

Modern Cell Theory

The modern tenets of cell theory include the following:

- All known living things are made up of cells.
- The cell is the fundamental unit of structure and function in living things.
- All cells come from preexisting cells by division.
- Cells contain hereditary information (DNA) which is passed from cell to cell during cell division.
- All cells are basically the same in chemical composition.
- All energy flow (metabolism and biochemistry) of life occurs within cells.
- Some organisms are unicellular, made up of only one cell.
- Other organisms are multicellular, composed of countless number of cells.

- The activity of an organism depends on the total activity of independent cells.
- As with any theory, its tenets are based upon previous observations and facts, which are synthesized into a coherent whole via the scientific method.

Cell Organization and Size

All living cells have three things in common. They have an outer plasma membrane, deoxyribonucleic acid (DNA), and cytoplasm. The plasma membrane is a structurally distinctive surface membrane that surrounds all cells. Every cell is enveloped by a protective plasma membrane, which is the outer covering that encloses the cell's internal parts and separates its contents from the surrounding external environment, so that cell activities can go on apart from events that may be taking place outside the cell. Substances can still move across the membrane, which does not completely isolate the cell's interior but serves to regulate passage of materials between cell and environment. Cells exchange materials with the environment and can accumulate needed substances and energy stores. Cells have specialized molecules that contain genetic instructions. In most cells, the genetic instructions are encoded in deoxyribonucleic acid, more known as DNA. The DNA is to be found inside the cell, along with molecules that can copy or read the inherited genetic instructions DNA carries. A semifluid matrix called *cytoplasm* fills the interior of the cell. The cytoplasm contains all of the sugars, amino acids, and proteins the cell uses to carry out its everyday activities. Although it is aqueous medium, cytoplasm is more viscous than water, owing to the high concentration of proteins and other macromolecules. It consists of a thick, jelly-like fluid, the cytosol, and various other components. Typically, cells have internal structures, called *organelles*, that are specialized to carry out metabolic activities such as converting energy to usable forms, synthesizing needed compounds, and manufacturing structures necessary for functioning and reproduction.

Although most cells are small, some quite large cells do exist. Their sizes vary over a wide range. A few cells, including the yolk of chicken eggs, can be seen with the unaided eye but most cells are so

small that they can only be seen with a microscope and must be measured in very small units. The surface-to-volume ratio is responsible for the small size of cells. As a cell's size increases, its volume increases much more rapidly than its surface area. The ratio is a physical relationship. It dictates that as the linear dimensions of a three-dimensional object increase, the volume of the object increases faster than its surface area does. For a spherical cell, surface area is proportional to the square of the radius, whereas the volume is proportional to the cube of the radius. Thus, if the radii of two cells differ by a factor of 10, the larger cell will have 10^2 , or 100 times, the surface area, but 10^3 , or 1,000 times, the volume of the smaller cell. In another example, if a round cell grew like an inflating balloon so that its diameter increased to four times the starting girth, the volume inside the cell would be 64 times more than before, but the cell's surface would be just 16 times larger. The cell would not have enough surface area to allow nutrients to flow inward rapidly, or for wastes or cell products to move rapidly outward.

The sizes and shapes of cells are related to the functions they perform. Some cells—such as the protozoan called the *amoeba*, and white blood cells—change their shape as they move about. Sperm cells, male reproductive cells, have long, whiplike tails, called *flagella*, for locomotion. Nerve cells have long, thin extensions that enable them to transmit messages over great distances. The extensions of some nerve cells in the human body may be as long as one meter. Other cells, such as certain epithelial cells, such as those that form the skin and line the intestines, are almost rectangular and are stacked much like building blocks to form sheetlike structures.

Cell Function

Cells organize living things. They keep chemical processes tidy and compartmentalized so individual cell processes do not interfere with others and the cell can go about its business of metabolizing, reproducing, and so on. As noted earlier, cell components are enclosed in a membrane which serves as a barrier between the outside world and the cell's internal chemistry. The cell membrane is a selective barrier, meaning that it lets some

chemicals in and others out, and in doing so maintains the balance necessary for the cell to live. The cell surface provides the only opportunity for interaction with the environment, because all substances enter and exit a cell via this surface. The membrane surrounding the cell plays a key role in controlling cell function.

Cell Types

All living organisms can be sorted into one of two groups depending on the fundamental structure of their cells. These two groups are the prokaryotes (prokaryotic cells) and the eukaryotes (eukaryotic cells). Prokaryotic cells are typically smaller than eukaryotic cells. In fact, the average prokaryotic cell is only about one-tenth the diameter of the average eukaryotic cell.

Prokaryotic Cells

Prokaryotes are organisms made up of cells that lack a cell nucleus or any membrane-enclosed organelles. Prokaryotic cells (prokaryotic means *before the nucleus*) are small cells that lack complex interior organization. They consist of cytoplasm surrounded by a plasma membrane that confines the contents of the cell to an internal compartment, with a characteristic cell wall that may differ in composition depending on the particular organism. In some prokaryotic cells, the plasma membrane may be folded inward to form a complex of membranes along which many of the cell's metabolic reactions take place. The plasma membrane of a prokaryotic cell carries out some of the functions organelles perform in eukaryotic cells. Nothing separates the cell's DNA from other internal cell parts. Prokaryotes have no distinct interior compartments; they lack a nucleus (although they do have circular or linear DNA) and other membrane-bound organelles (though they do contain ribosomes). Many prokaryotes have flagella, long fibers that project from the surface of the cell. Prokaryotic flagella, which operate like propellers, are important in locomotion. The dense internal material of the bacteria cell contains ribosomes, small complexes of ribonucleic acid (RNA), and protein that synthesize polypeptides, most lack the membrane-bounded

organelles characteristic of eukaryotic cells. The ribosomes of prokaryotic cells are smaller than those found in eukaryotic cells. Prokaryotic cells also contain storage granules that hold glycogen, lipid, or phosphate compounds. Bacteria and a microscopic organism called *archaea* are the only prokaryotic cells. A typical anatomy of prokaryotic cell might contain the following parts: cell wall, plasma membrane, cytoplasm, flagella and pili, nucleoid, and plasmid.

Eukaryotic Cells

Eukaryotes are organisms made up of cells that possess a membrane-bound nucleus (that holds genetic material) as well as membrane-bound organelles. The eukaryotic (*true nucleus*)

organisms have cells with membrane-bound nuclei containing chromosomes composed of chromatin. They occur in plants (from algae to angiosperms) and animals (from protozoa to mammals). The hallmark of the eukaryotic cells is compartmentalization. This is achieved through a combination of an extensive endomembrane system that weaves through the cell interior and by numerous organelles. In their cytoplasm are tiny compartments and sacs called *organelles* (*little organs*). One organelle, the nucleus, contains the DNA of a eukaryotic cell that carries out specialized functions. The nucleus, composed of a double membrane connected to the endomembrane system, contains the cell's genetic information. The eukaryotic cell has its own control center, internal

Figure 1 Structure of an Animal Cell

transportation system, power plants, factories for making needed materials, packaging plants, and even a *self-destruct* system. Biologists refer to the part of the cell outside the nucleus as *cytoplasm* and the part of the cell within the nucleus as *nucleoplasm*. Various organelles are suspended within the fluid component of the cytoplasm, which is called the *cytosol*. Therefore, the term *cytoplasm* includes both the cytosol and all the organelles other than the nucleus. The many specialized organelles of eukaryotic cells solve some of the problems associated with large size, so eukaryotic cells can be much larger than prokaryotic cells. Eukaryotic cells also differ from prokaryotic cells in having a supporting framework, or cytoskeleton, important in maintaining shape and transporting materials within the cell. Though the eukaryotic cells have different shape, size, and physiology; all the cells are typically composed of the following parts: cell wall, plasma membrane, cytoplasm, nucleus, nucleolus, chromosomes, ribosome, vesicle, endoplasmic reticulum (ER), Golgi apparatus, cytoskeleton, lysosome, centrioles, and mitochondria.

The Structure of Cells

Cell Wall

The outermost structure of most plant cells is a rigid layer called the *cell wall*. It is composed mainly of carbohydrates such as cellulose, pectin, hemicelluloses and lignin, and fatty substances such as waxes. Ultrastructurally, the cell wall is found to consist of a microfibrillary network within in a gel-like matrix. The microfibrils are mostly made up of cellulose. There is a pectin-rich cementing substance between the walls of adjacent cells, which is called the *middle lamella*. The primary cell wall is formed immediately after the division of a single cell into two cells. Many kinds of plant cells have only primary cell wall around them. In certain types of plant cells, such as those that constitute the tissues phloem and xylem, an additional layer is added to the inner surface of the primary cell wall at a later stage. Called the *secondary cell wall*, it consists mainly of cellulose, hemicellulose, and lignin. In many plant cells, there are tunnels running

through the cell wall called *plasmodesmata*, which allow communication with the other cells in a tissue. The cell wall constitutes a kind of exoskeleton that provides protection and mechanical support to the plant cell. It determines the shape of plant cell and prevents it from desiccation.

Plasma Membrane

Every kind of animal cell is bounded by a living, extremely thin and delicate membrane called the *cell membrane*, *plasmalemma*, or *plasma membrane*. Membranes divide the eukaryotic cell into compartments, and their unique properties enable membranous organelles to carry out a wide variety of functions. For example, cell membranes never have free ends; therefore, a membranous organelle always contains at least one enclosed internal space or compartment. These membrane-enclosed compartments allow certain cell activities to be localized within specific regions of the cell. Compartmentalizing also allows many different activities to go on simultaneously. Membrane-enclosed compartments keep certain reactive compounds away from other parts of the cell that they might adversely affect. Membranes allow cells to store energy. A difference in the concentration of some substance on the two sides of a membrane is a form of stored energy or potential energy. The plasma membrane is a selectively permeable membrane; its main function is to control selectively the entrance and exit of materials. This allows the cell to maintain a constant internal environment or *homeostasis*. The cell membrane regulates the crossing of chemicals in and out of the cell in several ways: by *diffusion* (the tendency of solute molecules to minimize concentration and thus move from an area of higher concentration toward an area of lower concentration until concentrations equalize), *osmosis* (the movement of solvent across a selective boundary in order to equalize the concentration of a solute that is unable to move across the boundary), and *selective transport* (via membrane channels and membrane pumps). As particles of substance move across the membrane from the side of higher concentration to the side of lower concentration, the cell converts some of this potential energy to the chemical energy of *adenosine triphosphate* (ATP)

molecules. This process of energy conversion is a basic mechanism that cells use to capture and convert the energy necessary to sustain life.

Cytoplasm

Within the plasma membrane is the cytoplasm, occupying the space between the plasma membrane and the region of DNA. It consists of a thick gel that surrounds the organelles, the cytosol, and various other components. Cytosol, the matrix of the cytoplasm, constitutes the cell's true internal milieu. The cytosol serves to dissolve or suspend the great variety of small molecules concerned with cellular metabolism such as glucose, amino acids, nucleotides, vitamins, minerals, oxygen, and ions. Cell biologists have identified many types of organelles in the cytoplasm of eukaryotic cells. Among them are the ER, ribosomes, Golgi complex, lysosomes, peroxisomes, vacuoles, mitochondria, and chloroplasts.

ER. The ER is a transport network for molecules targeted for certain modifications and specific destinations, as compared to molecules that float freely in the cytoplasm. The ER has two forms: the rough ER, which has ribosomes on its surface that secrete proteins into the ER, and the smooth ER, which lacks ribosomes. The smooth ER plays a role in calcium sequestration and release.

Ribosome. The ribosome is a large complex of RNA and protein molecules. Each consists of two subunits and acts as an assembly line where RNA from the nucleus is used to synthesize proteins from amino acids. Ribosomes can be found either floating freely or bound to a membrane (the rough ER in eukaryotes or the cell membrane in prokaryotes).

Golgi apparatus. The primary function of the Golgi apparatus is to process and package the macromolecules such as proteins and lipids that are synthesized by the cell.

Lysosomes and peroxisomes. Lysosomes contain digestive enzymes (acid hydrolases). They digest excess or worn-out organelles, food particles, and engulfed viruses or bacteria. Peroxisomes have enzymes that rid the cell of toxic peroxides. They are involved in lipid metabolism and detoxify harmful compounds.

Vacuoles. Vacuoles store food and waste. Some vacuoles store extra water. They are often described as liquid-filled space and are surrounded by a membrane.

Some cells, most notably the amoeba, a protozoan, have contractile vacuoles, which can pump water out of the cell if there is too much water. The vacuoles of eukaryotic cells are usually larger in those of plants than of animals.

Mitochondria and chloroplasts. Mitochondria are self-replicating organelles that occur in various numbers, shapes, and sizes in the cytoplasm of all eukaryotic cells. Mitochondria play a critical role in generating energy in the eukaryotic cell. Respiration occurs in the cell mitochondria, which generate the cell's energy by oxidative phosphorylation, using oxygen to release energy stored in cellular nutrients to generate ATP. Chloroplasts can only be found in plants and algae, and they capture the sun's energy to make ATP through photosynthesis.

Nucleus

The nucleus is the most prominent organelle in the cell. The nucleus is often described as a cell's master control center. It is also a protective *isolation chamber* for DNA, the genetic material. Nucleus is usually spherical or oval in shape and centrally located component which controls all the vital activities of the cytoplasm and carries the hereditary material the DNA in it. Because of its size and the fact that it often occupies a relatively fixed position near the center of the cell, some early investigators guessed long before experimental evidence was available that the nucleus served as the control center of the cell. The nucleus encloses the DNA of a eukaryotic cell. DNA contains instructions for building a cell's proteins. Those proteins in turn determine a cell's structure and function. In a human cell, there are 46 DNA molecules that together would be more than six feet long if they were stretched out end to end. Most cells have one nucleus, although there are exceptions.

The basic structure of the nucleus is composed of the

Nuclear envelope, which consists of two concentric nuclear membranes (an inner nuclear membrane which is lined by nuclear lamina and an outer nuclear membrane which is continuous with ER) that separate the nuclear contents from the surrounding cytoplasm. The envelope surrounds the fluid part of the nucleus (the nucleoplasm), and many proteins are embedded in its layers.

Nuclear pores, which consist of protein complexes, regulate the passage of materials between nucleoplasm and cytoplasm.

Nucleoplasm, the fluid interior portion of the nucleus.

Chromatin, which includes all the DNA molecules and their attached proteins; it appears as a network of granules and strands in cells that are not dividing. The chromatin has two forms: euchromatin and heterochromatin. Euchromatin is the well-dispersed form of chromatin which takes lighter DNA stain and is genetically active, that is, it is involved in gene duplication, gene transcription, and phenogenesis or phenotypic expression of a gene through some type of protein synthesis. Heterochromatin is the highly condensed form of chromatin which takes dark DNA stain and is genetically inert.

Chromosomes, composed of the individual DNA molecules and their attached proteins. *Nucleolus* which is a cluster of the RNA and proteins used to assemble ribosome subunits. It is the site where ribosomes are manufactured.

Cytoskeleton

Scientists watching cells growing in the laboratory see that cells frequently change shape and that many types of cells move about. The *cytoskeleton* is a dynamic internal framework made of microtubules, microfilaments, and intermediate filaments. The cytoskeleton provides structural support and functions in various types of cell movement, including transport of materials in the cell.

The Question of Viruses

Although there is no precise definition of what separates the living from the nonliving, it is widely accepted that because viruses consist not of cells, but only of DNA and RNA surrounded by a protein shell, they are not living organisms but complex biological mechanisms. Viruses lack a plasma membrane and metabolic machinery for energy production and for the synthesis of proteins. In consequence, viruses can only reproduce inside a suitable host cell, which may belong to animals, plants, or bacteria. Thus, a virus may be defined as an infectious, subcellular, and ultramicroscopic particle representing an obligate cellular parasite

and a potential pathogen whose reproduction (replication) in the host cell and transmission by infection cause characteristic reaction in the host cells. Outside the host cells, viruses are just like nonliving inert particles and, like salt or sugar, they can be purified, crystallized, and placed into jars on a shelf for years. They use their own genetic program for reproduction but rely on the raw materials (i.e., amino acids and nucleotides) and biosynthetic machinery of the host cells for their multiplication.

CHEMISTRY

Chemistry is understood as the set of scientific and technological practices based on analysis and synthesis that transform substances. Many of these substances have been and are of enormous

social importance, for example, when they are marketed as new materials or as medicines that improve and prolong human life.

As we know it today, chemistry is the result of the multiple legacies of a thousand years that, embodied in trades, influenced the daily life of all cultures, helping to build everywhere a material culture. It is still surprising that practices as different as that of the blacksmith and metallurgy, the healer and pharmacy, the potter and ceramics, and the baker and biotechnology have come together to end up merging, barely three centuries ago, in a common field: chemistry, by which practice substances are analyzed and transformed, in both small and large quantities, and over short or long spans of time. The following sections of this entry examine the origins and advances of theories and practices in chemistry.

Beginnings

It should be noted at the outset that analysis and synthesis of substances have been foundational for chemistry.

The analysis of substances, long associated with the concept of purity, has been a primary concern, if not an obsession, for chemists. Because substances found in nature cannot be considered pure, the separation of their constituent parts, the isolation of what is wanted, has been a constant in chemical practices, from their beginnings in the ancient tradition of alchemy, which spans four millennia and three continents, up to the present day. Among contemporary scientists, it is clear that there is no such thing as pure substances. Instead, there is a model of pure substance that has been built at the interface of technoscience over the years. What we have direct access to is a *predominant* substance mixed in minor or very minor amounts with other, different substances. Purity depends on our technical ability to identify impurities. Often, the modifications in chemical practices are the result of experimental innovations, associated with the incorporation of new instruments, rather than by the introduction of a new theory.

Through the operation of technical-chemical systems, human beings, as willing agents, have obtained substances that do not occur in nature, such as dynamite, aspirin, nylon, chlorofluoroalkanes, and the millions of artificial substances

that constitute a supnature, and which are philosophically called *artifacts*. There are no new substances—or artifacts—without action and without design. They are not only the result of an intentional human action, they also have a meaning embedded in a specific historical context. Since its millennial origin, through the trades, the main way in which chemists today *know* is by *doing*, and this chemical practice characterized by action has always increased the world's complexity. Chemistry professionals (a few million people around the world) make fundamentally new substances. Through their synthesizing practices, the number of such substances grew from several hundred in 1800 to more than 150 million at the beginning of the 21st century, most of which are on the market. And more than 15,000 new ones are being added every day, that is to say, one every 6 seconds. The synthesis of new substances makes chemistry an extraordinarily productive science. *Chemical Abstracts*, the database that informs us about most of the publications in this discipline, have reported practically the same number of publications as all the other sciences put together. This tremendously successful quality of chemical practices, this proliferation of artifacts, has caused an ethical debate about their impact on the world.

It should be noted that a disciplinary knowledge is always connected to a social context of transmission and to a social group, in this case the chemical community, which reproduces itself. For this reason, what we currently call chemistry, both academic and industrial, can only be understood taking into account its major transformations throughout history.

Chemical Practices: Pluralism, Theories, and Models

Chemistry is, therefore, a relatively young discipline that has integrated a multitude of millenary trades, today transformed into technosciences. Chemistry is about the changes in substances, whether in small or very large amounts. The process through which this happens is called a *chemical reaction*, in which one or more substances, the reactants, change to one or more different substances, the products. The time spans of these

reactions vary: They can occur almost instantaneously or over a prolonged period. Chemistry itself can be recognized as a practice—that is to say, a series of coordinated and shared activities (rules, reasons, techniques, purposes, beliefs) that are disciplined through the change of *correct* norms or procedures, and which have a stable structure that can reproduce itself through various learning processes. Some of the norms and procedures have changed slowly and some others quickly. Chemistry is recognized as a practice because the examination of the reasoning in chemists' ongoing work, particularly in experimental work, rests upon tacit knowledge, such as cannot be expressed in words. As in any industrial business, pragmatism is also required.

The individual ideal agent—the scientist—is replaced by a specific practitioner inside a specific community, for example, a chemical industry within a particular context.

According to some observers, chemistry fits better with models than with theories. Models are built to explain and to predict certain aspects of the world—with a specific goal, related, for example, to a certain chemical practice, as in substitution reactions. Because in chemistry, models are also mediators between the world and ourselves, which means that they function not only as representations but also as means of intervention; for example, Berzelian formulas as paper tools in 18th-century organic chemical practice were originally written H_2O for water or $\text{C}_2\text{H}_6\text{O}$ for ethanol. Different models for the same field of application can coexist and usefully complement each other, for example, in actual acid–base reactions, in contrast to theories that have been characterized as abstract conceptual objects with a logical structure.

In the scientific practice of chemistry, the chemical experiment is carried out in the laboratory. Chemical practices—analysis and synthesis—are different from other scientific practices, particularly those in physics. By participating in a practice, one knows what to do and what to say. Chemical practices are related to the historian of science Thomas Kuhn's *exemplars*, that is to say, the collection of problems, both theoretical and experimental, shared and solved by a specific community at a particular historical moment, which are generally found in professional

publications, academic papers, patents, and especially in a given discipline's textbooks. Apprenticeship in the regimented discipline of the chemical community allows the transmission of purposes and also the possibility of improving the practices themselves. Chemical practices do not try to discover how matter is constituted; what they mainly seek is to build new substances or to improve the social applications of the already known. For chemists, reality is found in the entities that explain chemical practices, such as molecular orbitals, rather than in the underlying physical theories, like quantum mechanics.

In accepting that the history of chemistry can be reconstructed from the practices carried out by different communities, pluralism is required. In other words, the facts emanating from small research laboratories, greatly amplified through industrial processes, related to multiple purposes but limited by the complexity of the chemical systems themselves, demand pluralism.

Pluralism supports that there is more than one way to success. The pluralism of purposes in chemical practices for some practitioners consists in analyzing the composition of a certain plant, whereas for some others, the purpose is to synthesize a new substance similar to the one found in the plant; and for some others to produce it in large quantities or in shorter time; and for still others verifying that it does not pollute the environment; hence, the idea of monism identified with a single scientific method is rejected.

Although Kuhn, in *The Structure of Scientific Revolutions*, treated the chemical revolution (marking the birth of this discipline as an independent science) as a clear example of a paradigm shift, his proposal has since been debated. In his discourse, there is scant discussion on experimental work and the use of instruments, a matter on which philosophers and historians of science have worked intensively in recent years. In a challenge to the Kuhnian picture, this means that during those historical periods that have been characterized as revolutionary, not all previous concepts are abandoned, let alone the experimental procedures, which are transformed from within by shifting the questions and the acceptable answers—after which new subdisciplines have appeared. In other words, following a major historical chemical transformation, different chemical practices are

introduced with new subdisciplines, although some exemplars remain and others change. This continuity and the rupture process are further explained in the next section through a brief history of chemical practices.

Here, it is important to recognize that the theoretical discoveries of chemical communities throughout their history have received different names: theories (e.g., Bronsted–Lowry acid–base theory), equations (e.g., Arrhenius equation), laws (e.g., constant proportions law), principles (e.g., Le Chatelier principle), and models (e.g., Lewis atomic model). Since chemical models allow a more successful interpretation of plural chemical practices, from now on, they will be used in this entry.

A Brief History of Chemical Practices

Chemistry emerged as a science, with robust and widespread laboratory and industrial practices in Europe, in the mid-18th century. Since then, it has undergone four major transformations, each characterized by the emergence of new subdisciplines like organic chemistry, physical chemistry, instrumental chemistry, and organometallic chemistry, among others.

With the waning of alchemy, there was a transitional period known as *protochemistry*. This can be characterized by the construction of at least three models capable of explaining what we know today as chemistry. The mechanistic model of particles developed by Robert Boyle; the compositional model developed by G. E. Stahl, which considered that chemical reactions, particularly those of combustion, were carried out from the presence of a substance called *phlogiston* in everything that contained it; the model of affinities developed by E. F. Geoffroy, which collected the empirical experience by which some substances were more inclined to combine with each other.

Chemistry as we know it today began in 1754 when the highly successful lecturer Joseph Black improved the analytical balance and isolated carbon dioxide from magnesium carbonate, in what can be recognized as the first quantitative chemical reaction. Over a decade later, Henry Cavendish improved the hydropneumatic tank and isolated a new gaseous substance not contained in natural air. Hydrogen was the first gas recognized as such. Antoine. Lavoisier is still considered a

key figure in this period, merging two independent and different chemical traditions, continental analytical chemistry and British pneumatic chemistry. With his definition of an element as the last unit of empirical analysis, he realized his ambition to reform and improve the chemical nomenclature. With the development of his calorimeter, the oxygen model to explain combustion reactions and the determination of the model of conservation of matter (commonly known as *law of conservation of matter*), the way of new chemical practices was cleared.

In 1749, John Roebuck and Samuel Garbett pioneered the industrial production of sulfuric acid by the lead chamber process. Subsequently, sulfuric acid became a very important chemical commodity, and its national production was used as a good indicator of the industrial strength of each country. Nicolas LeBlanc patented the method for the large-scale production of sodium carbonate, obtained from sulfuric acid and sodium chloride. Sodium carbonate was used mainly in the manufacture of soaps, glass, and paper. The production of hundreds of tons of both substances per year meant the beginning of industrial chemistry and its impact on the environment.

Alessandro Volta's invention of the electric battery in 1800 was followed by a multitude of experiments in which some researchers passed electricity through different objects and substances. One of them, Humphrey Davy, stood out for this activity by the isolation of many elements, among them sodium (Na), magnesium (Mg), calcium (Ca), and strontium (Sr). The birth of electrochemistry was important, but John Dalton's 1803 proposal of the atomic model for the structure of substances was more important; the proposal was supported, extended and partially consolidated by Jön Jacob Berzelius, an extraordinary Swiss chemist who gathered the greatest amount of atomic (and molecular) weights. Berzelius discovered several elements and suggested the electrochemical model of the chemical bond and the nomenclature of the elements that we use today.

In those days, not everyone accepted the existence of the chemical atom as a chemical entity. For instance, in France, the model of equivalents allowed an explanation of chemical reactions (mainly those of neutralization) without one having to accept the atomic model.

In 1828, the synthesis of urea by Friedrich Wöhler and the concept of isomerism heralded the beginning of organic chemistry. Since then, not only has the composition of chemicals been valuable, but the structure has also become very important. Shortly thereafter, Berzelius separated chemistry into inorganic and organic, the latter being interpreted with Charles Frédéric Gerhardt's types model, instead of the electrochemical bond model proposed by Berzelius himself. The electrochemical model indicated that the formation of all substances was due to the attraction between opposite electric charges, and it was successful with inorganic substances but a failure with organic substances. For this reason, many chemists accepted the vitalist model that held that through a vital force, different from the principles of inanimate objects, such as salts and inorganic minerals, complex organic substances were formed. However, this model collapsed with the synthesis of urea. Thus, for many of the following decades, chemical practices were separated by those who worked with inorganic substances and those who did so with organic substances.

The distinction between atoms and molecules was established in Karlsruhe, Germany, in September 1860, at the First International Congress of Chemists. The meeting was convened by some renowned personalities of that time who yearned to reform and enhance the language of chemistry. The purpose was not achieved, but after the meeting, some participants shared different *exemplars* that materialized in textbooks. Two of those exemplars related to analytical instruments: the *kaliapparatus*, developed by Justus von Liebig for the determination of the minimum formulas of the organic substances, and the polarimeter, used by Louis Pasteur to characterize optical isomerism until then only identified in organic substances. Chemistry was a European public activity. Different models were developed to explain new reactions and new chemical properties, like aromaticity. On the other hand, and since the participation of Stanislao Cannizzaro in Karlsruhe, molecules were clearly differentiated from atoms. Dmitri I. Mendeleev, another attendee to the event, using the valence model and atomic weights, built his famous periodic table. Until today, different models developed around the original concept of valence played a significant role in chemical practices.

In 1874, independently of each other, Jacobus Henricus van't Hoff and Joseph Achille Le Bel explained optical isomerism in molecules from the asymmetry of the carbon atom. Since then, the molecule has been the most important chemical entity. Many of the theoretical doubts were dispelled, while the industrial advances due to the discovery of the mauve dye by William Henry Perkin accelerated, particularly in Germany, the creation of a transnational chemical industry. Meanwhile, in England, the Alkali Act of 1863 was published to stop the discharges of hydrochloric acid into the atmosphere. Thus, chemistry, originally inorganic, had a subdiscipline broader than itself, organic chemistry, and this was its first big transformation.

The German university model that closely linked *pure* and *applied* research was copied in many European countries. Among all sciences, chemistry was the first in which experimental work during its teaching became mandatory. At that time, compulsory education was imposed in many European countries, and schools began to be built and managed by governments. Meanwhile, everything that could be synthesized and marketed was being produced. As an example, the respected German pharmaceutical company Bayer did so. In addition to aspirin, they commercialized cocaine and heroin. In Sweden, Alfred Nobel invented dynamite, and controlled explosions began to change the surface of the planet. In 1868, spectroscopy, developed by Robert Bunsen and Gustav Kirchhoff, allowed the discovery of the element helium (He) in the Sun.

Through analysis and synthesis, organic chemists could copy molecules that were originally in plants and animals and then produce entirely new molecules. Substitution models were used to explain specific chemical reactions. European societies first, then the rest of the world, were flooded with new dyes, materials, and medicines from the powerful German chemical industries. In Germany, as the number of colleges and universities with chemistry departments increased significantly, so did the numbers of their teachers, researchers, and students.

Chemists gradually incorporated more instruments in their laboratories and measured more accurately. Thermodynamics were well recognized. Physical chemistry and chemical physics,

the new specialities of both chemistry and physics, was under way. In 1887, Friedrich Wilhelm Ostwald and J. van't Hoff founded the first journal devoted to this subdiscipline. In the United States, chemical engineering emerged around the concept of unit operations. Arthur D. Little recognized that the majority of chemical processes were different combinations of a small number of operations like heating, cooling, distilling, drying, and so on, and his influence grew accordingly.

With his cathode ray tube, the British physicist J. J. Thomson discovered the electron, and the chemical community accepted that atoms could be divided. The research and characterization of isotopes by Francis William Aston using his mass spectrograph, together with the discovery of radioactivity, produced a turning point in the practice of chemistry. The recognition of the existence of atomic nuclei and electrons, the new entities of chemistry, gave rise to models (e.g., by Gilbert N. Lewis and Walther Kossel) that explained the nature of the chemical bond, as well as ions and radicals. In chemical practices, and in its exemplars, a priority of entity realism over theory realism can be recognized: Long before an appropriate theoretical representation was developed, chemists denoted their scientific objects as ions or radicals. The reality of atoms and molecules stopped being discussed. With spectroscopy and X-rays, electromagnetic radiation occupied an important place in chemical thought, increasingly influenced by the advances that were taking place in physics. It was clear that beneath the omnipresent materiality of the chemical substances, there was a reality that only physicists could access by techniques that were being developed.

Against the easy commercialization of any substance, a usual practice at the beginning of the 20th century around the world, in the United States, the Food and Drug Administration was established with the intention of regulating the local food and medicine market, a rule that later became global.

The outcome of the First World War, in which the United States participated decisively, confirmed that world geopolitics were changing. Although Germany lost the war, the German officer Fritz Haber developed the most important

techno-scientific process in the history of mankind, the artificial synthesis of ammonia, a fundamental substance in the production of fertilizers and explosives. Chemical practices are not ethically neutral. This synthesis gathered knowledge from different chemical, physical, and engineering practices. The American atomic model of Lewis faced the European model developed by quantum physicists. The first one could explain the chemical bond, fundamental to chemical practices, whereas the second one, spectroscopy, became fundamental to physics practice. Both models were the result of their time and of the ambitions of their creators. This was the second major transformation of chemistry, which entailed a different feeling about the world.

In 1945 at the end of the Second World War, the president of the National Science Foundation of the United States, Vannevar Bush, published the report *Science, the Endless Frontier*, in which he openly requested the federal government to finance science research in American universities and to give support to the companies that had supplied materials and equipment to the U.S. Army. With the adoption of this proposal, chemical laboratories changed more than they had done in the previous 300 years. From that moment, referred to as the *instrumental revolution*, the use of the next instruments became widespread in chemical practices: electrophoresis and ultraviolet, visible, infrared and nuclear magnetic resonance spectrometers; X-ray crystallography; and particularly since 1956, mass spectrometers. Meanwhile, chromatographs came to occupy a place in chemical laboratories' tables. New equipment industries were created following the military logic of the standardization of parts, which facilitated their consumption. The new subdiscipline of instrumental chemistry appeared. Robert Burns Woodward took advantage of the arrival of new instruments, such as nuclear magnetic resonance, in his research on synthetic chemistry. That allowed him, and some others, the preparation and characterization of more complicated products, many of them of great biological and medical importance. The synthesis of morphine, cholesterol, cortisone, strychnine, penicillin, and chlorophyll shared the onset of tranquilizers (such as chlordiazepoxide and diazepam), as well as contraceptives. The total synthesis of vitamin B₁₂ is a milestone in the

history of chemistry. Plenty of chemists in many countries worked for 11 years to synthesize this complex molecule with nine asymmetrical carbon atoms. Besides, commercial macromolecules changed the material world. The post–World War II period marked the beginning of the plastics era. Different research groups around the world undertook the application of thermodynamics and chemical kinetics to the systematic study of these materials.

The new subdiscipline of molecular biology emerged through the integration of chemistry, biology, and physics to answer a question: How is genetic information transferred from one organism to another? Molecular biology was trying to discover general physicochemical models that govern vital phenomena whereby macromolecules, especially proteins, became the principal focus. Since its origin, molecular biology has depended upon the design, provision, and maintenance of complex and expensive instruments.

At that time, computers were incorporated into chemical research practices and with them the programs that allowed chemical calculations. Many chemists, championed by Linus Pauling and Robert S. Mulliken, started to think about the structure of matter in terms of quantum mechanics. They did so considering some of the principles of quantum mechanics, incorporating broadly empirical information from chemistry practices. Quantum chemistry appeared as a new subdiscipline of chemistry, with new educational challenges. Instrumental chemistry, molecular biology, and quantum chemistry, with their own models and practices, characterize the third big transformation in chemistry.

The words *plastic* and *flexible* became commonplace and identified a socially valuable attitude, although the use of plastic objects led to huge consumption and to a massive global pollution problem. The new subdiscipline of organometallic chemistry, with its interest in the function of catalysts (a concept developed by Berzelius at the beginning of the 19th century), consolidated. At the end of the 20th century, the size and type of chemical objects (substances), the way in which they must be produced, and the time in which they are transformed were specified.

In 1974, Frank S. Rowland and Mario J. Molina published the results of their research on the effect

of chlorofluoroalkanes in the ozone layer. It was not the first time that chemical companies and governments around the world faced difficulties for industry's ability to pollute the environment, but at that moment, the damage and the risk were unequivocally global. In this sense, a couple of years earlier, the use of the insecticide DDT in the United States was banned as a result of the extensive information coming from a new instrument, "the most sensitive, easily portable and inexpensive analytical device in existence," the electron capture detector, invented and refined by J. Lovelock. After a strong struggle with the chlorofluoroalkanes chemical industry, where Molina and Rowland played an active role, the political response to ozone layer depletion was the Montreal Protocol. Signed in the 1980s by more than 200 countries, it was the first universally ratified treaty in UN history. So after the publication of Rachel Carson's book *Silent Spring* in the 1960s, the foundation of the U.S. Environmental Protection Agency in the 1970s and the Montreal Protocol, green chemistry as a new subdiscipline was born.

At that moment, the community learned how to make chemical reactions in less extreme conditions (in terms of pressure, temperature, and solvents) than those used hitherto. Chemical practices approached conditions that allow life and decreased the manufacture of potential pollutants. The construction and handling of large and different molecular aggregates gave rise to supramolecular chemistry. Close to this subdiscipline is another one: *nanochemistry*. This subdiscipline refers to the possibility of using chemical synthesis knowledge to build molecular aggregates of specific size, shape, composition, or surface, and it has multiple applications today in medicine, cosmetics, and materials. The origin of nanochemistry is related to the discovery of *fullerenes*, so called, in 1984 by Robert Curl, Harry Kroto, and Richard W. E. Smalley, and the subsequent synthesis of carbon nanotubes. At the same time, physicists at IBM designed the scanning tunneling microscope and the atomic force microscope instruments that allow *seeing* atoms and manipulating them individually at very low temperatures. In 1999, Ahmed Zewail was awarded with the Nobel Prize in Chemistry "for his studies of the transition states of chemical reactions using femtosecond spectroscopy." Although there are

chemical phenomena that last for billions of years, the most basic processes take place at few femtoseconds (1×10^{-15} s). This was the fourth big transformation.

Perhaps the biggest change in the chemical industry took place in pharmacy. Since the second half of the 19th century, many of the European dye companies were transformed into pharmaceutical houses. At the end of the 20th century, more than half of the world's medical research was conducted in the United States. Some of the most important developments in this short period were the use of recombinant DNA technology and the use of combinatorial chemistry for the design of medicines. Furthermore, three Swiss companies (Ciba, Geigy, and Sandoz) merged into the largest global business fusion in history, creating Novartis.

Concluding Remarks

After the four major transformations characterized, among other things, by the appearance of new, multiple, and important subdisciplines, all of them with their own models, chemistry is in need of redefinition. Consider what was stated about chemistry in the original French Encyclopedia, one of the chief works of the Enlightenment era, edited by Denis Diderot (1751, vol. 3, p. 408):

Chemists are distinct people, still very few, with their own language, their laws, their mysteries, and living almost isolated in the midst of great people hardly curious about their business and expecting nearly nothing from their industry. . . .

Clearly, this is no longer the case. In its relatively short history, the contribution of the chemical industries to widespread degradation of the natural environment cannot be ignored and has indeed become a matter of grave worldwide concern. Finally, in the 21st century, a clear and detailed acknowledgment of the history of women's contributions to chemistry, as well as the other sciences, is long overdue.

CHURCH-TURING THESIS

The Church-Turing thesis, properly understood, is a thesis about the semantic relationship between a group of linguistic expressions. It is a thesis for which there can be no mathematical proof, but it is generally considered to be beyond reasonable doubt and is almost universally accepted by mathematicians and philosophers of mathematics. The thesis is that a certain many-membered set of precisely defined mathematical expressions, which are coextensive with each other, are coextensive with the nonmathematical expression *effectively computable*, as that expression is used by mathematicians. The fact that there are many members of the set of precisely defined mathematical expressions is of utmost importance. To enable readers to understand what the thesis, as stated,

means, the purpose of this entry is to enable them to appreciate the importance of this latter fact.

This entry first outlines the general notion of a function, which it is crucial to understand if one is to understand the Church-Turing thesis. Then, the term *effectively computable* is introduced, followed by a number of the most important members of the set of precisely defined mathematical expressions, viz. *general recursive*, *λ -definable*, and *Turing computable* (these are the expressions discussed by Alonzo Church and Alan Turing in 1936, the year in which they independently introduced the thesis). The meaning of the thesis is then explained using the notions and terms introduced. The term *Turing computable* is then further explicated by giving an example of how the term is mathematically defined, and the entry finishes with a brief discussion of the significance of the thesis, illustrated by a further example given in terms of Turing computability.

Functions

The set of natural numbers, traditionally named N , is the set containing 0 and all of the positive numbers used for counting (sometimes 0 is excluded, but it is included here). So N contains infinitely many members: 0, 1, 2, 3, 4, and so on. For every member of N , there is another member of N that is 1 greater than it, called its *successor*. For example, N contains the number 3, so it contains its successor, the number 4. And N contains the number 3,450, so it contains its successor, the number 3,451. The *successor function* [here called $s(x)$] is the function that associates every natural number with its successor. So, $s(x)$ associates 0 with 1, 1 with 2, 2 with 3, and in general n with $n + 1$. The *domain* of a function is the set of objects for which the function is defined, so as $s(x)$ is defined for all natural numbers, its domain is N . The *range* of a function is the set of things which it associates members of its domain with, so because every natural number other than 0 is the successor of some other natural number, and because $s(x)$ associates every natural number with its successor, the range of $s(x)$ is the set of all natural numbers excluding 0. The members of a function's domain are called its *arguments*, and the members of its range its *values*. Thus, $s(x)$ has the value 1 for the argument 0, the value 2 for the

argument 1, the value 3 for the argument 2, and in general the value $n + 1$ for the argument n .

$s(x)$ has a single argument place. That is, it takes single objects (i.e., individual numbers) from its domain as arguments. But there is no restriction on how many argument places functions can have. For example, the *addition function* (here called $SUM(x,y)$) has two argument places; it is the function that associates every ordered pair of (not necessarily distinct) natural numbers x and y (written as $\langle x,y \rangle$) with their sum. For example, $SUM(x,y)$ has the value 5 for the arguments $\langle 2,3 \rangle$ (in this case, the argument places are filled by two distinct members of its domain) and the value 72 for the arguments $\langle 36,36 \rangle$ (in this case, both argument places are filled by the same member of its domain). Nevertheless, each function has a fixed number of argument places, called its *arity*. So, $s(x)$ has an arity of 1 and $SUM(x,y)$ an arity of 2. Despite it being possible for a function to have n argument places, for any $n > 0$, it is required (by stipulation) that a function with an arity of n associates each n -tuple of arguments with a single member of its range. (In practice, this is no real restriction at all, however, for the range of a function can itself contain ordered tuples of objects, but this will be of no concern in this entry.)

The two examples of functions given above are functions from natural numbers to natural numbers. Despite the fact that there is no restriction on the types of objects that functions can have in their domains or ranges, so shall be the further examples given in this entry. This is because the Church-Turing thesis only concerns those functions that can be represented as functions of natural numbers.

The Term Effectively Computable

The first of the linguistic expressions that feature in the Church-Turing thesis is the term *effectively computable*. This term is used by mathematicians to pick out a certain set of functions, but it is not a precisely defined mathematical term. It is applied to a function when there is an effective method for obtaining the value for any of its arguments. Such a method consists of a list of instructions that could be followed by a human working with only pen and paper that would, in principle and if

followed without error, provide the correct value for any of its arguments. The method must be completely explicit at each step and require no ingenuity nor information other than that contained within its steps to follow. It must be, in other words, the kind of method that could be implemented by an automated device capable of no independent thought. The method must also contain a finite number of steps, each of which must take a finite length of time to perform. Even with these restrictions, however, there are methods that no actual human being could practically perform. For example, there are methods that require more digits to be written down, in any numeral system, than there are atoms in the universe. And there are methods that, despite being finite, would take any actual human working as fast as they could until the heat death of the universe occurs to complete. But these are practical limitations of space and time, and they are ignored when talking about effective computation. In order for a function to be effectively computable, all that is required is that the method would, given enough space and time, and ignoring any other practical difficulties with its implementation, produce the correct value for any of its arguments.

Any effective method must represent the natural numbers using some numeral system or other (so far in this entry, the familiar Arabic numerals—"0," "1," "2," etc.—have been used). So long as there is an effective method for translating between one system and another (as there is for all known systems), it makes no difference which is used. But for practical and illustrative purposes, certain simple systems are often easier to work with. Later, when discussing Turing machines, the tally system will be used, in which a particular number n is represented by $n + 1$ strokes (so 0 is represented by "I," 1 by "II," 2 by "III," etc.). But it can also be used fruitfully now to give a simple one-step example of an effective method for producing the correct value for any argument n of $s(x)$:

1. To find $s(n)$, write down $n + 2$ strokes.

For $s(3)$, for example, one would write down five strokes, "IIII," which represents the number 4. It is intuitively clear that this method meets the requirements laid down for being an effective

method, and so, this shows that $s(x)$ is effectively computable.

Effectively computable is often said to be an intuitive or informal term, and it is sometimes said to be vague. What is certainly true is that it is not a precisely defined *mathematical* term. This is because it is defined in terms of expressions (e.g., *requiring no ingenuity to follow*) that are not themselves precisely defined mathematical terms. This seems to be what is meant by those who say that the term is intuitive or informal, and so, one should have no qualms about admitting that it is so. But it is less clear whether the term is vague. Syntactically, the term is a predicate and so has what is known as an *extension*, in other words a set of things that it applies to. A term is vague, in the full sense of the word, if it has an indeterminate extension, that is, if there are some things such that it is indeterminate whether the term applies to them or not. For example, the expression *bald person* plausibly has no determinate extension; there are some people for whom it is unclear whether or not they are bald, and so, it is indeterminate whether such people fall into the extension of the term. The term *effectively computable* may or may not be vague in the same way, but whether or not it is depends upon contested issues in the philosophy of language and metaphysics that there is not enough space in this short entry to discuss. So, for the purposes of this entry, the possibility that the term is vague in this sense should be merely noted.

The Terms General Recursive, λ -definable, and Turing Computable (Among Others)

In 1888, the German mathematician Richard Dedekind introduced a way of defining a set of precise functions now known as the *primitive recursive functions*, which was studied more fully by a number of other mathematicians in the 1920s and early 1930s (most notably by the Hungarian mathematician Rózsa Péter). *Recursion* in mathematics, understood intuitively, is a procedure whereby new functions are obtained by feeding the values of functions back into themselves as arguments (possibly multiple times), and the primitive recursive functions are defined by just such a procedure. A particular set of basic

functions that can be shown to be effectively computable in a trivial fashion (as $s(x)$ was previously shown to be so) are laid down. Then, two procedures for defining new functions from these basic functions, *composition* and *primitive recursion*, are introduced. These procedures are finite and require no ingenuity to carry through, so any function defined from the basic functions using them is also effectively computable. So, it follows that any function that is primitive recursive is effectively computable, and so every function in the extension of primitive recursive is in the extension of effectively computable. It does not follow, however, that any function that is effectively computable is primitive recursive, so it does not follow that there are no functions in the extension of effectively computable that are not in the extension of primitive recursive. And indeed, a number of functions that are effectively computable but not primitive recursive were discovered in the late 1920s. The most well known of these is known as the *Ackermann function*, after the German mathematician Wilhelm Ackermann, who discovered it in 1928.

In 1934, the great Austrian mathematician Kurt Gödel gave a series of lectures at Princeton University where, developing work by the French mathematician Jacques Herbrand, he extended the recursive method by adding a new finite procedure, *minimization*, to the two existing procedures. Gödel called the functions that can be defined from the basic functions using the new procedure along with the old the *general recursive* functions and showed that the Ackermann function is general recursive. Thus, Gödel introduced a new precisely defined mathematical predicate that was known to have in its extensions all primitive recursive functions and at least some others that are effectively computable but not primitive recursive. However, Gödel did not show that *general recursive* and effectively computable are coextensive (i.e., that they have exactly the same extension), and Gödel remained unconvinced that this is in fact so until after the publication of a seminal paper in computability by the British mathematician Alan Turing in 1936. Before Turing's paper, however, came another seminal paper by the American mathematician Alonzo Church.

In the early 1930s, Church was working on the foundations of mathematics and, along with

his fellow U.S. American Stephen Kleene, developed a formalism called the λ -calculus, in which it is possible to precisely define a set of functions known as the λ -definable functions. The method is again finite and requires no ingenuity to perform, so it was known that all λ -definable functions are effectively computable. Then, in 1936, Kleene showed that the terms *general recursive* and λ -definable are in fact coextensive, in other words, that every general recursive function is λ -definable, and vice versa. This result was followed in the same year by the publication of Church's seminal paper on computability, where the Church-Turing thesis was first introduced (although it is customary to refer to Church's version of it simply as *Church's thesis*). The methods used to define the λ -definable functions and the general recursive functions are very different, but both seemed to Church to be equally natural ways of cashing out the notion of what it is for a function to be effectively computable. So the fact that the two turn out to be coextensive was taken by Church to be strong evidence that they do in fact capture that intuitive notion.

Later in 1936, Church's conjecture was bolstered when the British mathematician Alan Turing published his seminal work on computability. In his paper, Turing laid down yet another finite method for defining a precise set of functions that involved no ingenuity to perform. He thus introduced another mathematical predicate (now known as *Turing computable*) that had as its extension a precise set of functions. Turing's method involves defining an idealized machine known as a *Turing machine*, which carries out computations by following instruction to perform a finite series of simple actions from an explicitly defined list. A function is said to be Turing computable if and only if it can be computed by such a machine. Turing's method, although strictly defined, matches the notion of an effective method more closely than those used to define *general recursive* and λ -definable, which gave it a more compelling *prima facie* claim to capture that intuitive notion than those previous methods. But, moreover, Turing was able to show that *Turing computable* is also coextensive with λ -definable and so with *general recursive* too. So, at this point, three distinct ways of cashing out the intuitive

notion of effective computation were known, all of which gave rise to predicates that turned out to be coextensive.

Since 1936, a significant number of other ways of cashing out effective computation in strict mathematical terms have been laid down, and each has been shown to define a predicate that is coextensive with the predicates *Turing computable*, *general recursive*, and λ -*definable*. It is this fact that has convinced mathematicians and others of the truth of the Church-Turing thesis. But what precisely is the thesis? In its strongest and most simple form, it is simply the thesis that *effectively computable* is coextensive with *Turing computable* (or *general recursive*, or λ -*definable*, or with any of the other coextensive mathematical predicates that have been defined). But the possible vagueness of *effectively computable*, noted earlier, indicates that there is a weaker version of the thesis in the vicinity. For anyone who believes that the predicate *effectively computable* is in fact vague (i.e., that it has an indeterminate extension), the thesis is not, strictly speaking, that *effectively computable* is coextensive with the precisely defined mathematical predicates. Rather, it is that its extension is satisfactorily close to the extension of those mathematical predicates. The most natural way of cashing out the weaker version of the thesis is to hold that (i.) every function that determinately falls into the extension of *effectively computable* also falls into the extension of the mathematical predicates, and (ii.) every function that determinately does not fall into the extension of *effectively computable* does not fall into the extension of the mathematical predicates. On the weak version of the thesis, the meaning of the mathematical predicates (in one sense of *meaning*) is precisification of the meaning of *effectively computable*, while on the strong version, the meanings are the same.

Examples of How Turing Machines Compute Functions

In this brief entry, it is not possible to give an exhaustive account of each of the mathematical methods for defining functions described in the preceding sections. However, as some familiarity with at least one method gives a greater understanding of the thesis, in this section, Turing machines are described in more detail, and two

simple examples of how they compute functions are given.

A Turing machine is an idealized computing device that is most often visualized as a small box on wheels that moves up and down an infinitely long tape that is divided into squares. Each square is marked with either a single cross or a single stroke, and the box has something inside it (it doesn't matter what) that is capable of reading whatever is on the square it is positioned above, and of performing one of five actions: (1) It can delete whatever is in the square and replace it with a cross; (2) it can delete whatever is in the square and replace it with a stroke; (3) it can move the box one square to the right; (4) it can move the box one square to the left; and (5) it can halt. The thing in the box passes through a series of states, and at each moment what it does is determined by whatever is in the square it is reading and what state it is in. Two kinds of states, an *initial state* and an *end state*, can now be defined. An initial state is a state in which the box is positioned over a particular square S ; in the squares to the left of S , there is nothing but crosses; in S and the squares to its right, there may be strokes that form blocks separated by no more than one cross. So, for example, the tape in an initial state might look like this: “. . . XXXI-IXIIIXIIIXXXXX . . .” but cannot look like this: “. . . XXXIIIXXIIIXIIIXXX. . .” An end state is a state in which the box is positioned over a particular square S ; in the squares to the left of S , there is nothing but crosses; in S and the squares to its right, there may be strokes that form a single block, but no more, followed by crosses. So, for example, the tape in an end state might look like this: “. . . XXXIIIIIXXX. . .” but cannot look like this: “. . . XXXIIIXIIIXXXXX. . .” The tally system introduced earlier is now used such that blocks of strokes are taken to represent the natural numbers. So, for example, the series “. . . XXXIIIXX. . .” printed on a portion of tape represents the number 3, and the series “. . . XXXIXIIIXIIIXXX. . .” represents the n -tuple $\langle 0, 2, 3 \rangle$.

A Turing machine computes the value v of an n -tuple of arguments $\langle a_1 \dots a_n \rangle$ for a function f by having a series of instructions that are such that, if it were started in an initial state that represents $\langle a_1 \dots a_n \rangle$, it would halt in an end state that

represents v . Let us take the functions $s(x)$ and $SUM(x,y)$ once more as examples. Consider the following instructions:

State 1: If there is a stroke in the current square, go right and stay in State 1. If there is a cross in the current square, delete it and replace it with a stroke, and go into State 2.

State 2: If there is a stroke in the current square, go left and stay in State 2.

If there is a cross in the current square, go right and halt.

Given these instructions, a Turing machine started in an initial state on a tape representing 3 (e.g., "...XXXIIIIXXX..."), halts in an end state on a tape representing 4 (e.g., "...XXXIIIIXXX..."). If started in an initial state representing 6 (e.g., "...XXXIIIIIIXXX..."), it halts on a tape representing 7 (e.g., "...XXXIIIIIIIIXXX..."). In general, if started in an initial state representing n , it will halt on a tape representing $n + 1$. So, a Turing machine can compute $s(x)$.

As the functions get more complex, so do the instructions needed that enable Turing machines to compute them. Even the instruction for the (relatively) simple $SUM(x,y)$ is fairly complex. But the following description adequately illustrates how a Turing machine can compute $SUM(x,y)$. It starts in an initial state representing $\langle x,y \rangle$ (i.e., on the leftmost stroke of a block of x strokes that is followed by a single cross and a block of y strokes) and halts in an end state representing the sum of x and y (i.e., on the leftmost stroke of a single block of $x + y$ strokes followed by crosses). So, if started over the leftmost stroke on a tape that looks like this: "...XXXIIIIIIIIXXX..." (representing $\langle 3,2 \rangle$), it halts over the leftmost block on a tape that looks like this: "...XXXIIIIIIIIXXX..." (representing 5). One set of instructions that provides this result tells the thing in the box to move right through the first block of x strokes, past the cross that separates it from the second block of y strokes, until it reaches the rightmost stroke in this latter block. It then tells the thing in the box to delete the rightmost stroke and replace it with a cross. It then tells it to travel left back to the cross it passed before, and to delete it and replace it with a stroke, before continuing to the left to halt

over the leftmost stroke in the block of x strokes. As it is possible to provide these instructions using the five actions given, a Turing machine can compute $SUM(x,y)$.

Significance of the Church-Turing Thesis

The significance of the Church-Turing thesis derives from the fact that it has been shown that there are particular functions of natural numbers that do not fall into the extension of the precisely defined mathematical predicates described above. The Church-Turing thesis (in both its strong and weak form) thus entails that these functions are not effectively computable. Both Church and Turing independently discovered such functions and on the basis of their discoveries independently established that a problem posed by the German mathematician David Hilbert, known as the *Entscheidungsproblem*, is unsolvable. The problem was to show that there is an effective method for deciding whether an arbitrary formula, framed in a system of what is known as *first-order logic*, is provable from the axioms of the system. Church and Turing were able to reduce this problem to the problem of showing that certain functions are computable, and so by showing that particular such functions are not computable, they established that there could be no such method.

Probably the most well-known example of an uncomputable function is the *halting function* (called here " $h(x,y)$ "), which Turing showed to be uncomputable in his 1936 paper. This function, $h(x,y)$, can be described fairly simply in terms of Turing machines. So, given that Turing machines have already been described, this entry concludes with a brief informal proof that $h(x,y)$ is not Turing computable and so by the Church-Turing thesis not effectively computable either.

First, note that there are infinitely many possible Turing machines (consider: there is a Turing machine that computes every function in the series $f(x + 1)$, $f(x + 2)$, $f(x + 3)$...). Next, note that Turing machines can be *enumerated*. This means that each of the infinitely many Turing machines can be associated with a distinct natural number. So, suppose E is an enumeration that does just this. Now, we can describe $h(x,y)$ as the function that

has the value 0 for arguments $\langle x, y \rangle$ if the Turing machine associated with the number x by E and started with input y halts and has the value 1 otherwise.

To see that $b(x, y)$ is not Turing computable, start by assuming that there is in fact a Turing machine, T_1 , that computes $b(x, y)$ and so halts in an end state representing 0 if the Turing machine associated with x by E halts given input y , and in an end state representing 1 otherwise. Now, consider another Turing machine, T_2 , that given a single number as input first copies that number on the tape (so, e.g., started on a tape that looks like this: “. . . XXXIII XXX. . .” it first produces a tape that looks like this “. . . XXXIII XXXIII XXX. . .”) before returning to the leftmost stroke, whereupon it follows exactly the same instructions that T_1 follows, except that it has the following instructions in place of those that tell T_1 to halt (i.e., it has two extra states s and $s + 1$):

State s : If there is a stroke in the current square, go right and go into State $s + 1$.

State $s + 1$: If there is a cross in the current square, go left and go into State s . If there is a stroke in the current square, go left and halt.

So, given input x , T_2 behaves just as T_1 does for input $\langle x, x \rangle$, except that when T_1 halts on a tape representing 0, T_2 instead goes into an infinite right-left loop, and so never halts. Now, consider that T_2 will be associated with a natural number n by E and consider what happens if we use T_1 to compute the function $b(n, n)$. There are only two possible results:

A: T_1 halts in an end state representing 0 given input $\langle n, n \rangle$.

B: T_1 halts in an end state representing 1 given input $\langle n, n \rangle$.

Now, given our assumption that T_1 computes $b(x, y)$, we have:

If T_1 halts in an end state representing 0 given input $\langle n, n \rangle$, then T_2 halts given input n .

If T_1 halts in an end state representing 1 given input $\langle n, n \rangle$, then T_2 does not halt given input n .

But now, from what was said about how T_2 operates, we also have:

If T_2 halts given input n , then T_1 halts in an end state representing 1 given input $\langle n, n \rangle$.

If T_2 does not halt given input n , then T_1 halts in an end state representing 0 given input $\langle n, n \rangle$.

So from A, together with (i.) and (iii.), we can derive:

A*: T_1 halts in an end state representing 1 given input $\langle n, n \rangle$.

And from B, together with (ii.) and (iv.), we can derive:

B*: T_1 halts in an end state representing 0 given input $\langle n, n \rangle$.

So, because A* contradicts A, and B* contradicts B, we can conclude that our assumption that T_1 computes $b(x, y)$ must be false. So, no Turing machine can compute $b(x, y)$, so this function is not Turing computable, and so by the Church-Turing thesis, it is not effectively computable either.

CLIMATE SCIENCE

Climate science is the branch of scientific inquiry that studies the Earth's climate. Roughly speaking, an area's climate is the long-term average of its prevailing weather conditions. Climate science studies how the Earth's atmosphere, oceans, land surface, ice sheets, and biosphere interact in creating its climate. It is thus a field that draws on and integrates different kinds of scientific expertise. In the 20th century, we became aware of our own influence on the climate, which brought climate science to prominence. In particular, the burning of *fossil fuels* such as coal and petroleum releases gases into the atmosphere that have a warming effect on the climate. This anthropogenic (human-caused) warming will have significant negative effects for people and ecosystems around the world, and continued emissions will worsen these effects. Much of climate science from 1970 into the 2020s has been devoted to understanding this climatic change and helping policymakers decide how to mitigate its harm or adapt our societies to it.

This entry continues with an overview of climate science. It then reviews some theoretical questions in the foundations of climate science, such as the definition of *climate* and *climate change*. Climate change is a major social problem, and the following section sets it up as the background for the coming discussion. There follows a discussion of the methods of climate science and theoretical issues associated with them. Next come two major areas of climate policy: mitigation and adaptation. The entry closes with a discussion of late 20th-century climate skepticism.

Overview

The English word *climate* comes from the Greek *klima*, meaning region, and the roots of climate science lie in describing regional variations in temperature and habitability. In this sense, writing on the variation of regional climates goes back at least as far as ancient Greece and the writings of Herodotus. But the origins of modern climate science are usually dated to the 17th century, with the invention of the modern thermometer and barometer. It is around this time that

climate came to mean roughly what it does today: a pattern of weather.

Modern climate science studies the Earth's climate system. According to the Intergovernmental Panel on Climate Change (IPCC), the climate system is made up of five major components which interact to create the Earth's patterns of weather. The first component is the atmosphere: the layers of gas surrounding the planet. Second, the hydrosphere: the parts of the Earth's surface covered in liquid water, including all the oceans, seas, and lakes. Third, the cryosphere: the parts of the planet covered in ice, including the ice sheets, sea ice, lake ice, and snow cover. Fourth, the lithosphere: the rocky crust of the Earth itself, its tectonic plates, their movement, and associated seismic and volcanic activity. Fifth, the biosphere: the collection of all the Earth's living organisms and their ecosystems. Life requires certain conditions in the atmosphere, hydrosphere, cryosphere, and lithosphere and in turn shapes them.

The climate system changes over time, owing to the interaction between these five systems and because of *external* influences upon it. Climate science focuses on three external influences: solar radiation, volcanic eruptions, and human activity such as greenhouse gas emissions and changes in how we use land. Of these, only the Sun is truly external to the Earth's climate system, but this is the standard usage.

Climate science aims to explain and predict the events, changes, and workings of this climate system. In the second half of the 20th century, climate science developed rapidly and gained in prominence. This was due to the development of computers and the discovery of anthropogenic climate change. Computers, with their capacity for rapidly processing massive amounts of data, made it possible to simulate the dynamics of the atmosphere and ocean, creating new capabilities for explaining and predicting climate phenomena. Anthropogenic climate change is a global challenge that has created an urgent need for understanding of the climate system.

Foundational Questions

What is the definition of *climate*? While the vague notion of *prevailing weather conditions*, or *pattern*

of *weather* has been in use since the 19th century, it is difficult to make this definition precise.

The most common definition, as noted earlier, is that a region's climate is its *average weather conditions* over a suitably long period, typically 30 years. While the weather in Hyderabad at mid-day on March 1, 2021, is characterized by a temperature of 33°C, humidity of 25%, northerly wind of 2 m/s, and so on, Hyderabad's climate is an aggregate of these weather conditions. It might be characterized by describing average temperatures (or perhaps average daily highs and lows), average humidity, rainfall, and so on, for a time of year. These quantities (temperature, precipitation, etc.) are known as *climate variables*. It is standard to calculate these averages over 30 years and to use the recent historical record. So, the climate in Hyderabad in 2021 might be calculated from the historical records for climate variables in Hyderabad from 1990 to 2020.

One theoretical problem with this definition is that it can fail to capture marked climatic changes. The eruption of the volcano Mount Tambora in 1815 was the largest in human history: The ash, sulfuric acid, and water thrown into the atmosphere reflected enough of the Sun's radiation to cool the Earth. The eruption coincided with a natural low point in the Sun's radiation, and the combined effects led to the global average temperature falling by approximately 0.5°C. Over the next 3 to 5 years, crops failed due to the cold or the disrupted rainy seasons, which in turn led to rising food prices and famines. The 1810s are the coldest decade on record because of the 1815 eruption. It is natural to say that these were *changes of climate* and that the change occurred in 1815. But the 30-year average definition can't capture this kind of dramatic shift. At best, it allows for a gradual change, as the years 1815 through 1820 are included in the 30-year average.

This and other problems have led to a proliferation of technical definitions of climate and climate change of different kinds. One kind are *distributional* definitions: Climate is a distribution of climate variables over a period of time, subject to certain constraints concerning the internal and external conditions. Another kind are *ensemble* definitions, which also define the climate as a distribution of climate variables, but rather than

being a distribution over the past 30 years, this is a distribution over possible climates which are consistent with what we observe now. A third approach is common among climate physicists, who define climate relative to *models* of the Earth's climate (discussed below). These definitions reference the conditions in models rather than in real or possible climate systems, for example, by defining a climate as an attractor of a non-linear model.

The different definitions exist because scientists want different things from a definition of climate. Distribution definitions have been criticized for being overly statistical, and not referencing physical processes like solar energy flux and ocean currents, which drive climate processes. Ensemble and model definitions are criticized for being too abstracted from the Earth and its actual climate.

A related question is how to characterize the state of the climate. Scientists debate which quantities should be used, either in the distributions that feature in some definitions of *climate* or as a shorthand for talking about climatic change. For example, much focus is given to global mean surface temperature. Targets for climate change are frequently framed in terms of restricting the increase in mean *global surface temperature* (GST) to below some level, such as 2°C above preindustrial levels. But this single quantity is standing in as a representation of the state of the whole, very complex, climate system. There is a range of potential issues here. The first is that a single quantity is unlikely to serve as a good proxy for the state of such a complex system. Communicating about climate change and climate policy goals in terms of it may therefore be too crude or misleading. The second is that GST may not be the best way to represent even this aspect of the climate system: How much heat is accumulating in it? Instead, we may do better by focusing on heat changes in the oceans. But while this may better track some important physical processes, it worsens a third issue with GST: It is abstract and far removed from the changes of climate that people care about, and which policy is interested in mitigating or adapting to. These tend to be local changes, and in particular, damaging extremes of temperature or precipitation.

Climate Change as a Social Problem

Much of the interest in climate science since the mid-20th century is because of changes in the climate. According to the IPCC's fifth assessment report, released in 2014, changes in climate have caused impacts on natural and human systems on all continents and across the oceans. The most cited effect is an increase in GST: From 1880 to 2020, the Earth's temperature increased by about 1°C. This change may sound small, but it belies wide-ranging and significant changes at regional levels. Changes in extreme weather events from 1950 through 2020 have been attributed to climate change, including high temperatures, high sea levels, and heavy precipitation. These events have hurt or killed many people and damaged property. There have also been changes to precipitation patterns and melting ice. Many species have changed their geographic ranges and seasonal activities due to such changes. Agricultural crop yields have suffered negatively, and while there are regions in which agriculture has benefited from the changed climate, the negatives are more frequent than the positives.

Climate science has established that human activity is causing these climatic changes. Producing and burning fossil fuels emits gases such as carbon dioxide and methane. These are called *greenhouse gases* because they contribute to the greenhouse effect in which the atmosphere traps heat from solar radiation. While the greenhouse effect is natural and required for life on Earth, adding greenhouse gases to the atmosphere amplifies the effect and leads to a warming climate. This presents us with a social problem of global magnitude. Greenhouse gases are by-products of industrial processes that have been regarded as necessary for human life and flourishing since the industrial revolution. For example, most of our energy has been produced by burning fossil fuels. Limiting further climate change will require substantial and sustained reductions in emissions, which in turn will require significant changes in how we produce energy, manufacture goods, and transport ourselves and our goods.

Climate change is a collective action problem. This term describes a situation in which the best outcome is achieved if all individuals (and companies, countries, and communities) cooperate.

However, there are incentives and competing interests between individuals, which mean that this cooperation is difficult to secure. Here is a simple example: Reducing emissions from an industrial process like cement manufacturing is costly in the short term. So, if other firms begin to decarbonize, a cement firm that continues to use the polluting process will become comparatively more profitable. Securing cooperation can therefore require coordinating effort from outside the industry, in the form of government regulation. Because climate change is a global problem, this requires coordination between governments.

However, countries themselves have disagreed significantly over how to decarbonize. This is because of concerns about historical inequalities between countries, in terms of how much they emitted in the past and how this relates to injustices such as colonization. This is discussed in the Mitigation section later in the entry.

Another issue in addressing climate change is the fact that the harms of climate change will occur mostly in the future, while the costs to decarbonize must be paid now. There is a misalignment between which generations caused the problem, which must pay the price to fix it, and which will suffer the consequences. An important ethical question is thus: How do we weigh the interests of future generations against those of people living today? There is also a political problem: Leaders in democracies are accountable to voters who exist and vote today. Even if future generations' interests ought to be considered, it is unclear how to do so within the decision-infrastructure of early 21st-century democracy.

Methods of Climate Science

Observing Climate Change

Identifying climate change and projecting future changes to the climate require that we understand what it means for the climate to change. *Climate* is an aggregate notion, and the climate system is naturally varying all the time, so defining and detecting a change in climate is not straightforward. The IPCC defines *detection of climate change* as the process of demonstrating that climate has changed *and* that this change is unlikely to be due to internal variability. For example, one

might say that a change is detected in observations if the likelihood of that change occurring by chance due to internal variability alone is determined to be below 5%.

Detecting a change in climate thus requires something like the following process. First, one needs to estimate the internal variability of the climate system (to exclude this as a cause of any observed changes). This is made difficult by most of our reliable data coming from the 20th century, a period in which there were significant external changes, such as increasing emissions. As a result, estimates of climate variability are often obtained from models: The internal variability of the climate in a model is used as a proxy for the internal variability of the Earth's climate. But global climate models often show different levels of internal variability, which makes it difficult to settle on a standard for detection.

Nevertheless, as the effects of climate change grow, it becomes easier to detect. In 2020, a research paper published in *Nature Climate Change* made a startling announcement in its title: "Climate change now detectable from any single day of weather at global scale."

So what data are used to observe climate change? First there are meteorological observations. These are local weather data from the meteorological stations around the world. For example, temperature measurements are aggregated to calculate the GST, which is how we know that the GST has increased by 1°C from 1880 to 2020. Another source of direct measurement is the extent of glaciers. Globally and cumulatively, the thickness change of glaciers has decreased by about 12 meters between 1960 and 2010. The shrinking extent of Arctic sea ice, usually measured at its September minimum and March maximum, is another source of direct observation of global warming.

These data were all gathered relatively recently and so can only give us evidence of climate change in the period after around 1880. Climate scientists want to understand the state of the climate at earlier times and therefore use various proxy sources of data to make inferences about the historical state of the climate. For example, climate scientists study *ice cores*—long vertical pillars of ice cut out of ice sheets. These polar ice sheets formed from thousands of years of accumulated snowfall.

The weight of successive snowfalls compressed snow into ice, forming layers of ice that act like tree rings. By drilling deep (up to 1.5 kilometers), researchers can study how the composition of the ice changed and use this as a proxy for how the climate changed. Air trapped in the ice provides tiny samples of the atmosphere at the point when the ice layer formed. Changes in the presence of certain isotopes of oxygen in different layers gives an indication of changes in air temperature. Particles in the ice provide evidence of the composition of the atmosphere and past events like volcanic eruptions.

There are many theoretical challenges with such proxy investigations of the paleoclimate. One, which concerns ice cores, is limited geographic coverage: Ice sheets exist only at the poles. So, an inference is needed to go from proxy evidence about the past climate at the poles to the past climate of the planet. Another issue is that proxies often reflect the influence of many climate variables at one. Tree rings reflect all the influences on the tree's growth: the soil, precipitation, temperature, sunlight hours, and so on. This makes it difficult to use these proxies to study single climate variables and to calibrate climate models. Third, combining information from different proxies is challenging: Tree rings and ice cores give evidence about different regions, in different periods, and with different temporal resolution. It is a significant challenge to work out how to combine these data and what the resulting uncertainties are.

Models of the Climate

One of the most important tools of climate science is the simulation model. A model is a representation of a system, in this case the Earth's climate system. Climate science uses a spectrum of models, with different degrees of complexity and resolution.

At the most complex end of the scale are *general circulation models* (GCMs), which model the circulation of the atmosphere and oceans. They simulate this circulation in three dimensions and include interactions with the land surface and cryosphere. This is a difficult and complex process, which requires multiple forms of expertise and significant computing resources.

We can think of these complex simulation models as having the following parts. First is a structural–dynamical description of the system: a description of how it works and how it evolves from one state to another. For GCMs, this is a representation of the circulation of the atmosphere and oceans using equations from fluid dynamics. But, as noted earlier in the entry, the climate system also involves the land surface, cryosphere, biosphere, and the remainder of the hydrosphere, each of which has important dynamics. One major trend in climate science in the 2000s has been the development of more complex models capturing more of these factors.

These dynamical relations are captured with differential equations, involving variables (the main quantities of interest, like temperature and precipitation) as well as parameters (which are fixed quantities, supplied exogenously). Models are simplified and idealized representations and so do not attempt to accurately capture every aspect of the climate system. Instead, they use bits of theory—typically physics, in the case of climate science—to capture the most important dynamics of the climate.

The resulting equations involve variables that are continuous functions of space and time and are very difficult, if not impossible, to solve exactly. To solve them, scientists *discretize* space and time and create an algorithm for approximating the solution to the continuous equation. Spatially, this involves dividing the surface of the Earth into a grid. Temporally, it involves thinking of time as coming in discrete *steps*. One specifies the state of the system at a point in time and then calculates how the system will be after one step, at the next point in time. To do this, the continuous *differential* equations describing the atmosphere and oceans are transformed into discrete *difference* equations. Computers, using step-by-step methods, can then produce approximate solutions. The computer programs that explore this approximate behavior of the system are called *computer simulation models*.

This structural–dynamical part of the model captures parts of the system’s dynamics that the modeler (a) has a theoretical understanding of and (b) regards as important to their current purposes. Other parts of the system might be *parameterized*—that is, represented in the model not via a full

dynamical description, but in a simplified form. These simplified representations often take the form of a single number or set of numbers whose values are supplied by measurements, simple calculations, or other models. Clouds are an important example of a feature of the climate which has been treated via parameterization in GCMs.

Finally, a simulation requires a set of initial conditions, specifying the state of the system at the time the model is initiated. The structural–dynamical description, parameters, and initial conditions are sufficient information to *run* the model, that is, to perform the calculations required to specify later states of the system.

Simulation models raise interesting theoretical issues. First, the study of simulation models is a kind of indirect inquiry: Scientists study the models to learn about something else, the climate. Work is required to establish that this is a reliable form of inquiry. Scientists try to establish that their model does accurately represent the target system, by reproducing some of its known behavior. Typically, this involves simulating the past and seeing whether the model correctly *predicts* what happened. But if the climate itself is changing, does successfully simulating the past give us a reason to believe that the model’s predictions of a changed future climate will be accurate? The hope is that the model captures the mechanism driving the climate system, so that when the model is supplied with the right boundary conditions—in this case, the current and expected emissions—it will correctly simulate the future states of the climate. To test this, scientists use paleoclimate data (such as ice cores) to see whether the models capture the mechanisms that underlay past changes in the climate.

Second, it is common to encounter a range of different models representing the same system.

Such models might disagree over the structural relations in the system or over the values of parameters or initial conditions. A prominent example is the sixth Coupled Model Intercomparison Project (CMIP6) ensemble of global climate models. In some cases, such model *ensembles* may indicate disagreements among scientists; in others, they reflect variation in acceptable methods of model construction. In either case, the ensemble represents some of the scientific uncertainty about the climate system. Ensembles pose a

challenge for users of models, such as policymakers, who need to decide which model result to use for their decision.

One approach is to use many models at once, as in CMIP6. Such studies compare the results of different models and attempt to use the distribution of model results to generate more reliable results. There are different approaches to doing this. One is to use the average result. This could be computed by weighing all model results equally and calculating a simple average. Or the models could be weighed differently, perhaps according to their performance in predicting past data or based on their perceived reliability. In either case, there is debate as to why the *average* should be used. Another option is to look at the range of values spanned by the models and to act as though any of these is equally possible. This in effect turns the problem of multiple models from an epistemic problem (Which output is the right answer?) to a practical question (Which answer should one use for deciding?).

Climate Policy

Mitigation

One kind of policy targeting climate change is called *mitigation*. This refers to reducing future changes in the climate by targeting the causes of climate change. The goal, as the United Nations Framework Convention on Climate Change puts it in Article 2, is to stabilize “greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system.” In practice, this means reducing the release of greenhouse gases into the atmosphere, either by reducing sources of these gases or by increasing the capture of these gases. According to the IPCC, about 78% of the total greenhouse gas emission increase from 1970 to 2010 was due to carbon dioxide from the combustion of fossil fuels and industrial processes. Major sinks for these gases include the forests, soil, and oceans.

To reduce our greenhouse gas emissions, we will need to find substitutes for the burning of fossil fuels. In energy generation, this requires replacing coal- and gas-fired power stations with nonemitting sources of power such as solar,

wind, and geothermal energy. Reducing energy use is also important, as it will allow us to reduce emissions while we are still dependent on fossil fuels. Energy-efficient buildings, vehicles, and industrial processes are thus important areas of mitigation policy.

The development of *carbon sinks* is another important area. A carbon sink is any system that absorbs greenhouse gases from the atmosphere or prevents additional emissions. Often, discussions about developing carbon sinks also include avoiding processes that remove natural sinks, such as deforestation, desertification, and the loss of certain oceanic ecosystems. But this simply avoids worsening the problem rather than actively improving it. It is also important to increase the amount of carbon taken out of the atmosphere to develop new and expand existing carbon sinks. One option is carbon capture and storage, which refers to capturing the carbon dioxide released from large sources, such as power plants and industrial facilities, and storing it rather than allowing it to be released into the atmosphere. Another option is removing carbon dioxide that is already in the atmosphere through technological means.

Who should reduce their emissions, and who should pay for the development of carbon sinks? This is a question that goes beyond climate science and into the realm of climate justice, as we are asked to consider the just distribution of burdens in responding to this global challenge. Countries’ past contributions to the accumulation of greenhouse gases in the atmosphere are different and reflect their histories of industrialization and colonization. The G8 nations (the United States, Canada, United Kingdom, Germany, France, Italy, Russia, and Japan) are regularly attributed with more than 60% of all emissions to 2015, and some studies attribute as much as 85% of all accumulated emissions to them. Residents of these countries have some of the best living standards in the world, a fact that is deeply connected to their harmful emissions. By contrast, the least developed countries on Earth have not emitted very much, and many have argued that if they were to refrain from emitting activities, this would hinder their ability to develop and thereby ensure that their residents would never achieve comparable quality of life.

However, in the early 21st century, the pattern of emissions has shifted. India and China were in the top five CO₂ emitting countries in each year from 1991 to 2020, and China overtook the United States as the world's largest emitter somewhere around 2005. If one accounts for deforestation as a form of emission, Brazil and Indonesia have been top 10 emitters in the 2010s.

Different regions will face different kinds and levels of climate change, some of which will be more harmful than others. Historically marginalized people are expected to experience some of the worst consequences. Current climate projections expect developing countries in the Southern Hemisphere to receive some of the worst effects of climate change. The changing climate will also push people into poverty, as the climatic conditions supporting their livelihoods change. At an individual level, poorer people have fewer resources to recover from hardships and often lack insurance that could assist them. At a group level, historically disadvantaged populations are often last to receive relief after catastrophic events like hurricanes and floods. So, both internationally and intranationally, those who are least responsible for climate change are expected to face its worst consequences.

Adaptation

The second major category of policies for dealing with climate change is adaptation to the expected future climate. The goal of adaptation is to reduce our vulnerability to changes in the climate that might prove harmful, such as changes in the frequency and severity of extreme weather events, or sea-level rise. Adaptation efforts also aim to benefit from any opportunities afforded by climate change, such as changes in precipitation and a longer growing season. As the climate will change in very different ways in different places, adaptation policies are highly varied and location specific.

Adaptation efforts include changes to ecological, social, and economic systems as well as the development of infrastructure. In an area that is expected to experience significantly greater rainfall, for example, adaptation may involve improving stormwater drainage in the cities, altering

riverbanks and building flood defenses. For an area that is expected to experience tropical cyclones for the first time, adaptation may involve the development of early warning systems, changes to building codes, and the establishment of evacuation procedures. Adaptation is a necessary part of any climate policy: Even if emissions were to suddenly stop, the effects from already accumulated gases would continue to be felt for thousands of years.

Contestation and Skepticism

Climate skepticism refers to doubt in the social problem of anthropogenic climate change. It can take one of three forms. The first is doubt in the trend of global warming. The second is doubt about the attribution of this trend to human causes. The third is doubt about the impacts of climate change. Skeptical claims about the trend of global warming include the claim that the measurements are faulty because of the urban heat island effect. Skeptical claims about attribution include the claim that the warming observed is a product of natural variation and the claim that carbon dioxide does not lead to warming. Skeptical claims about impacts include those who think that warming will be entirely beneficial or that humans will naturally adapt to whatever changes occur without much disruption.

Particularly in the United States, the issue is politicized. Conservative and libertarian think tanks and lobbyists have been significant promoters of climate skepticism. In the 2010s, Republican Party voters were less likely than Democrats to rate climate change as a priority issue, and Republican politicians frequently questioned the reality of climate change. This may be the result of prioritizing ideological commitments to small government and the free market over the factual question of whether anthropogenic climate change is happening. Climate change is a global issue, and the kinds of mitigation and adaptation policies mentioned above have been associated with significant state intervention in the form of regulations, taxes, subsidies for new technologies, and large infrastructure projects. (These need not be the only tools for accomplishing mitigation or adaptation, but they

have been significant in proposals in the period 2000–2020.) Conservative opposition to climate action thus seems to follow from a sort of perverse syllogism: If anthropogenic climate change is real, then significant government action is necessary to enact the required mitigation and adaptation policies. But government action is never necessary! So anthropogenic climate change is not real.

Although these are political issues, they are of significant concern to climate scientists, science advisors and communicators, and academics studying the science–policy interface. Climate change is one of the great challenges of our time. It is an issue in which scientists have played, and continue to play, a crucial role in identifying the nature of the problem and its potential solutions. And yet a significant proportion of people do not trust these scientists. Political leaders have actively discredited the scientists and their work, thereby undermining efforts to prevent catastrophic climate impacts. We need better ways of negotiating contested political issues, like the role and extent of government, without undermining climate science and climate scientists.

COGNITIVE SCIENCE

Cognitive science is an interdisciplinary domain of investigation that explores how people perceive, understand, and store information about reality. It includes the study of psychology, anthropology, sociology, information technology, biology, linguistics, and neuroscience. It both benefits from these disciplines and contributes to their development. The interdisciplinarity and interrelatedness have led to a plethora of approaches as far as analyzing cognitive science is concerned. The most important of these are discussed in the sections that follow.

Cognitive Science and Methodologies

Systemic Approaches

Cognitive studies can be characterized by a diversity of approaches and tools that are used to conduct research in this discipline. First, since cognition itself involves the work and engagement of different systems, cognitive science can be described as the ability of various systems to cooperate. Systems in this case can be understood in different ways. One of them is to look at systems as a set of different disciplines that, together with their methodologies, form what is commonly known as *cognitive science*. The second way of looking at this issue is to investigate systems as sets of different individual and social identities, concentrating on micro-systems (e.g., one person) and/or more macro-systems (e.g., communities, groups). The systemic perspectives offer the opportunity to study diversified factors of different origin and their roles in creating, sustaining, or eliminating a given entity. Systemic theories furnish the possibility of studying cognitive science as an open system, depending on the environment and responding to its alterations; an open system utilizes inputs from the surroundings and sends outputs to the encompassing environs. Thus, systems can be investigated by taking their boundaries into account. As far as cognitive science is concerned, a demarcation line is difficult to establish due to the interdisciplinary character of methodology and scope of interest. However, boundaries can be observed between subdisciplines, each having some outstanding features and characteristic scientific approaches. The next option is to study systems through their processes. Thus, the dynamism of cognitive science can be investigated by observing various actions and events in systems.

Network and Hybrid Approaches

Apart from systemic approaches, network perspectives also focus on showing the complexities and interrelations of elements. An example is *actor-network theory* (ANT), one among several popular network perspectives, which stresses the role of living and nonliving entities in determining the performance of people and things. As previously stated, ANT can be used to study the

complexities of modern systemic realities. Narrowing the scope of interest to cognitive science, ANT can be used to discuss the role of living (e.g., workers, stakeholders) and nonliving elements (computers, telephones, etc.) in creating and sustaining cognition. *Social network analysis*, another network theory, stresses the relations between people taking part in any cognitive activity, paying attention to such processual issues as knowledge flow, communication, and innovation. It reflects the popular postmodern approach to the concept of cognition, with such aspects as changeability, interconnectedness, and relations being of crucial importance. By applying this approach, one may observe how social networks are created by different factors at individual and group levels and how they influence individual and group cognition.

Hybridity offers another perspective to cognitive studies. The aim of this approach is to highlight how each of the aforementioned stages determines the existence of the other one as well as their mutual performance. Cognitive studies as a discipline is shown not only as the sum of other layers but rather as a hybrid structure, with independent and unique features created by the coexistence of diversified elements.

Fuzzy-Trace Theory

One of the methodologies that can be used in examining cognitive behavior is the fuzzy-trace theory. As discussed by Valerie Reyna, meaningful parts are encoded in memory in two ways: verbatim representation and gist representation. Verbatim representation is related to an objective relation of what has taken place, whereas gist representation is a subjective perception of what happened. Gist representation depends on one's identity, gender, social role, life experience, and genetic aspects; the same information can be perceived differently by two people regarding their attitude toward risks.

Heuristics and Schemas

Heuristics, on the other hand, enables one to find the needed answers to important questions or the best methods to deal with novel situations. Cognitivists are also interested in studying framing, which concerns whether a given piece of

information is presented in a positive or negative way. In that case, one's cognition is guided by the way risks or gains are visualized.

Schemas theory constitutes another key issue in cognitive science; schemas (schemata) encompass a set of concepts that facilitate the gathering, understanding, storing, and using of knowledge by arranging information in meaningful groups. Schemas can be subdivided by taking into account their function, such as describing people (person schemas), social roles (role schemas), or situations (event schemas).

Purpose

Cognitive studies could also be researched by taking into account the focus of investigation. For example, cognitivists study deficits in cognitive abilities. Such investigations facilitate the understanding of various illnesses such as Alzheimer disease and help patients who suffer from cognitive deficiencies. Apart from the aforementioned medical scope of investigation, cognitive science is used for commercial purposes. For example, such areas of study as advertising or branding benefit from knowledge of how customers perceive and understand marketing communication and make it possible to prepare, for example, commercials or advertisements that will meet the needs and expectations of the target audience. Another way of classifying cognition is by taking into account the type of situations; for example, risky situations involve different types of cognitive behavior. One of the key notions is memory that determines the way a concept is perceived and stored. Another field of investigation is motivation. This issue, being pertinent to such disciplines as education and management, facilitates the understanding of how to make learners or workers more eager to learn novel issues or work more effectively.

Research Scope

Another notion in cognitive studies is the scope of investigation. Cognition can also be researched by analyzing individual or social notions that determine the way cognition takes place. Analyzing the personal dimension, researchers are interested in how an individual perceives and understands reality. At this level, studies concentrate on such notions as gender, age, profession, and social and cultural

background. As far as the macro-approach is concerned, researchers are interested in social cognition, in the way a group perceives and reacts to a given stimulus. Moreover, researchers focus on studying how emotions determine cognition; for example, how people who are happy or stressed perceive a given notion. It should also be highlighted that although human beings constitute the primary focus of research in cognitivism, some researchers investigate the cognitive abilities of animals. For example, the LUCS Cognitive Zoology Group at Lund University in Sweden is interested in *cognitive zoology*, observing the cognitive functions of animals and how animals perform in different environments as well as how they learn and adapt to new conditions.

Linguistic Perspectives on Cognitive Science

Since language is among the most conspicuous representations of cognitive functions, the scope of investigation in linguistics is mainly on the cognitive rather than on the physical side of acquiring, understanding, and using language, being determined by individual and social factors. The long-standing interest in cognitivism (the latter being briefly defined as the science of studying the mind) has given rise to an area of studies called *cognitive linguistics*, focusing on mind-related processes connected with coding and decoding language-related content. The discipline of cognitive linguistics is studied in this contribution in two ways. First, the disciplinary perspective is applied, with such subfields within cognitive linguistics to, among others, language learning and teaching, translation, psycholinguistics, neurolinguistics, and sociolinguistics.

Language Education

Language learning and teaching focuses on how children learn their mother tongue and how one's native language accompanies the growth and maturation processes of individuals. Thus, it can be stated that cognitive linguistics has a developmental side, concentrating on how language changes together with an individual. This approach allows studying how people use language in different life situations and how various factors

determine the way one's linguistic repertoire is used. It is represented in, for example, the way individuals learn corporate discourse and professional jargon as well as in the introduction and execution of corporate linguistic policy in companies and organizations employing multilingual staff. The educational aspect of cognitive linguistics is also visible in the focus on teaching and learning foreign languages. The cognitive perspective makes it possible to understand how novel wording is mastered. Cognitivists interested in foreign language and teaching study the interrelation between a mother tongue and a new foreign language to observe how one's first language determines the acquisition of new tongues. Additionally, such factors as the age, gender, profession, and motivation of learners are taken into account in investigating their cognitive abilities. Cognitive linguistics is also interested in how the selected linguistic tools facilitate or hinder cognition. An example of such a communicative tool is metaphor; researchers investigate how symbolic language determines the understanding of texts. For example, such studies include the research on the role of metaphors in creating and disseminating novel or difficult information to a diverse audience. Another field of investigation is the role of figurative language in cross-cultural communication, aimed at serving diverse language users by relying on commonly known and understood symbols. It should be mentioned that cognitivists may also be interested in nonverbal symbolism, analyzing the influence of pictorial metaphors on the target audience.

Translation

Another subfield of linguistic studies researched by cognitivists is translation; the scope of investigation focuses on, for instance, how equivalents are selected by translators as well as what cognitive processes take place during interpreting.

Psycholinguistics, Neurolinguistics, and Sociolinguistics

Yet another discipline is psycholinguistics, which focuses on how a human being is able to produce, understand, and store a piece of a text or an utterance. A related field is neurolinguistics,

with its focus on how the brain and the nervous system influence the production, perception, and usage of linguistic elements. Some traces of cognitive investigation may be observed in sociolinguistics, which aims at showing the relation between the society and discourse.

Aspects of Language

Apart from the discussed domains, the division of cognitive linguistics into subfields may follow the well-known subcategorization used for linguistics, which stresses different aspects of language: semantics, syntax, and pragmatics. *Cognitive semantics* encompasses the interest of researchers in the way words and phrases are created, understood, used, and stored. Apart from the semantic dimension of cognitive investigations, researchers also study syntax and the way grammar is perceived and understood. *Cognitive syntax* may also prove useful for the studies on foreign grammar acquisition as well as the studies on how children formulate sentences. The last element, *cognitive pragmatics*, studies the relation between meaning and context by applying the cognitive perspective. Cognitivists are interested in investigating how the environment determines the way information is perceived and understood. For example, the same data may be comprehended differently in neutral and risky situations. The aspectual approach offers deeper ways of investigating such subdomains of linguistics as translation or language learning and teaching. Taking the issue of translation into account, semantics provides an insight into such translation elements as terms, whereas pragmatics offers information on the role of context in source and target texts.

Economic Perspectives on Cognitive Studies

Many modern companies are interested in cognitive and behavioral processes taking place at the internal and external level of business entities. The link between economics and cognitive studies is analyzed through such subdomains as cognitive management, cognitive cultural economics, behavioral economics, and cognitive marketing.

Cognitive Management

One field of cognitive interest that has been gaining popularity is the theory of *cognitive management*, pioneered by James Eicher, that focuses on behavioral and cognitive styles of managers to facilitate effective leadership and communication in groups; this area of studies is devoted to finding the best methods of managing people.

Cognitive Cultural Economics

The next domain is *cognitive cultural economics*. In the business world of the 21st century, the business-related disciplines of cognitive studies benefit from cooperation with other areas of research that are cognitive-oriented. One example of such a scientific alliance is the relation between cognitive management and cognitive linguistics. It is visible in the focus on how company discourse is used, perceived, and stored at both the individual and societal levels in companies. Thus, the main sphere of interest is to investigate how different stakeholders perceive the company both as individual human beings and a professional (societal) group. To discuss both the inner and outer dimension of organizational communication, the term *company identity* can be employed to investigate the cognitive complexities of managing discourse. Taking into account the multitude of factors shaping company identity, the focus should be on culture (especially its different elements observable in both individual and group levels) as the crucial identity marker. Regardless of the approach used to analyze the individual or social personality, identity is related to symbols (common values, things, and heroes), language (jargon, slogans, and humor), practice (common rituals, ceremonies, and activities), stories (common myths and legends), and various forms of physical expression (movement and architecture). All the abovementioned elements are created by individuals coming from different cultures and, at the same time, the aforementioned elements create the identity of cross-cultural companies and their representatives. Consequently, managerial cognitivists may analyze in greater detail the communicative aspect of company identity through the prism of cross-cultural differences and show the influence of the abovementioned elements on creating the linguistic dimension of identity in professional

settings. Cognition in that case is studied in a very broad sense, analyzing the response and perception of the entire spectrum of stakeholders, which including, among others, employers, employees, mass media, and residents of the town the company operates in.

Cognitive Economics

Another field of investigation benefiting from the interrelation between cognitive studies and the discipline itself is *cognitive economics*, which focuses on cognition in economic issues and decisions. As in the case of cognitive business, cognitive economics may also rely on the achievements of cognitive linguistics. Given that language shapes both individual and social performance—since it is not only a tool creating the economic reality but also the *recipient* of economic conditions—its dual nature makes it a key factor in any discussion on economy-related topics. For example, one of the economic issues researched in the literature is economic inequality, which can be discussed by taking into account different dimensions. For example, the micro-dimension focuses on the individual level of economic gaps between the person and their economic environment. The meso-dimension, depending on the context, can be related to an organization or a community and its economic position within a broader reality. By contrast, the macro-dimension focuses on the studied country and its place in the global economic world. However, no matter which field of investigation is taken under closer scrutiny, it is language (among other factors) that shapes the performance of individual human beings, communities, groups, organizations, and countries as well as determines their position in the global market. Since language is not only a tool of communication but also an instrument of exercising power or benefiting from some resources, its role in the field of economic inequality and international trade should become the focus of modern investigations as well.

Behavioral Economics and Cognitive Marketing

The elements of cognitive studies can also be traced in *behavioral economics*, which focuses on how different factors related to cognition determine economic decisions and market situations.

Taking the customer and product perspectives of business studies into account, such subfields as *cognitive marketing* can be enumerated. The classification can be taken further, by naming the subcategories of cognitive marketing, such as *cognitive branding* or *cognitive advertising*. The subdisciplines of cognitive marketing encompass the investigation of different cognition types. For example, since branding focuses on such dimensions as the verbal, visual, audio, and olfactory ones, cognitive branding is supposed to research cognition by paying attention to different kinds of stimulus and the overall effect, respectively.

Psychological and Sociological Perspectives of Cognitive Science

The interrelation between psychology, sociology, and cognitive science is visible in at least five subdomains. The first of them, *cognitive psychology*, can be defined as the field of study concentrating on mental processes since it provides an answer to how people perform different functions related to cognition, such as thinking, remembering, and selecting. Another subdomain, *cognitive sociology*, studies how social determinants influence the processes of understanding and perceiving the reality.

The psychological dimension of cognitive studies is also realized by paying attention to the process of decision making: *cognitive heuristics*. In addition, it should be mentioned that the psychological dimension of cognitive science can be analyzed by taking into account both healthy and unhealthy subjects, offering methods of releasing stress or fighting with diseases. Relying on modern achievements in cognitive behavioral therapy and hypnosis, Trevor Silvester introduced *cognitive hypnotherapy* for people whose professions demand high concentration, quick reactions to changing environments, and the necessity to face different stressors. Another field of interest in psychology is the relation between addictions and cognition. In that case, researchers representing mainly psychology and neuroscience investigate how the use of addictive substances determines the cognitive abilities of individuals.

Artistic and Philosophical Perspectives of Cognitive Science

The artistic sphere of cognitive science encompasses the approach connected with different domains of art and the way these types of arts can be perceived and understood. For example, *cognitive poetics* focuses on the application of cognitive psychology to the study of literary texts. *Cognitive aesthetics* concentrates on the emotions and feelings connected with artistic experience. It studies how individuals react to works of art, such as paintings, music, and imaginative literature. This aspect is also crucial for medical applications of art in facilitating clinical treatment or in marketing efforts to stimulate purchasing behaviors. Cognition has interested philosophers from the time of classical antiquity. The current representatives of philosophy who aim to observe the link between cognitive science and philosophy concentrate on the domains referred to as *philosophy of mind* and *cognitive philosophy*.

Intercultural Perspectives of Cognitive Science

Cognition also takes into account differences between cultures. Owing to the advancements related to modern technology and the consequently high mobility of people, ideas, and things, contacts with other cultures and access to culturally different products have become relatively easy. Consequently, a modern human being typically has a hybrid identity composed of different cultural elements and is constantly exposed to contradictory values and points of view. This may sometimes lead to cognitive dissonance, with novel attitudes held alongside, and in contradiction to, the older ones. When faced with a new situation, an individual may focus on cognitive egocentrism, stressing the superiority of their way of thinking over the ones shared by others. Intercultural differences are also connected with different viewpoints on such issues as humor, the role of family in one's life, attitudes to material world, and so forth. In addition, cross-cultural studies provide information on why people perceive and understand various

notions in different ways. For example, such issues as the openness to novelty or the role of tradition can be taken as a marker determining the way various notions are perceived. Cognitive studies in intercultural communication also encompass investigations of differences in perception and categorization of color and shapes. Another notion studied through the prism of cognition is symbolism; there are symbols that are culturally specific as well as the ones that are universal. As far as the methods of studying cognition are concerned, both qualitative and quantitative approaches may prove useful.

Neuroscientific Perspectives on Cognitive Science

Neuroscience constitutes one of the disciplines to which cognitive science is strongly related. The neuroscientific dimension of cognitivism focuses on how the brain and the nervous system determine cognitive and behavioral bodily functions. Applying both micro- and macro-approaches, neuroscientists are interested in how a given part of the brain, and the whole body as such, determine the cognition of human beings and animals. Cognitive abilities are studied by neuroscientists investigating different groups of people. For example, neuroscientific research focuses on the cognitive abilities of people following brain injury or who are experiencing neurodegenerative diseases. Such interest in cognitive disorders leads to a better understanding of the needs and possibilities of patients suffering from, for example, Alzheimer disease and other forms of senile dementia. Another application of neuroscientific investigation for cognitive purposes is seen in the fields of management and marketing. The aim of neuromanagement is to check the cognitive side of leadership, studying the way a given style is perceived and how that style determines the perception of tasks. As far as neuromarketing is concerned, researchers are interested in which parts of the brain are responsible for purchasing behaviors and how a presented stimulus may determine the subject's reaction to the merchandise.

Technological Perspectives on Cognitive Science

Modern advancements in technology have led to the growing interest in *cognitive computing*, focusing on creating machines that possess human-like abilities. *Cognitive ergonomics* focuses on the relation between people and machines, studying, for example, the interaction between individuals and computers. Technological dimensions also consider differences connected with the growing popularity of the Internet in contemporary society. Cognitive science is also interested in studying the differences in the way people behave in online and offline environments. One field of investigation focuses on those who spend a large amount of time online and how this influences human relations and cognition as such. Another topic of research is the role of social networking tools in creating relationships and group participation.

Tools Used in Cognitive Science

Given its multidisciplinary nature, cognitive science relies on tools originating in different disciplines. Among the biggest donors is neuroscience since it offers both invasive and noninvasive apparatus to study how the brain and the nervous system function. One of the most complex machines and, at the same time, the one that offers many ways of looking at the tissue under study is *functional magnetic resonance imaging* (fMRI), which aims at measuring brain activity by observing changes in blood flow. The subject is placed within a special tube where anatomical scans are performed, followed by measuring the responses of subjects asked to perform certain activities. The closed and limited space within the apparatus is for some a source of discomfort; moreover, people with claustrophobia may be altogether unable to take part in this type of testing. Another inconvenience that is often reported by subjects is the level of noise generated by the apparatus (people may receive headphones that limit to some extent the level of noise). A key advantage of this method, however, is that it is noninvasive and does not carry risk for the subject. However, the use of the contrast agent that is injected to enhance the

visibility of the area under examination should be treated with great care if subjects report an allergy or are determined to be allergic to the agent. Another tool used in cognitive studies is *electroencephalography*, which records brain activity when the subject is sleeping, resting, or performing some activity, depending on the purpose of testing. Still another technique is *transcranial magnetic stimulation*, in which a wire coil is used to induce magnetic field. It offers the possibility of observing how the brain functions and serves as a tool in treating certain neurological problems. It should be mentioned that not only the brain itself is observed in researching the cognitive and behavioral processes of human beings. For example, *facial electromyography* is used to observe facial muscle performance and record the emotions of subjects to presented stimuli. Another technique, that of measuring *galvanic skin response* (skin conductance), concerns the electrical features of the skin and is used to study the subject's responses to presented stimuli. It should be mentioned, however, that not all tools are noninvasive, and sometimes scientists must rely on the invasive ones. For example, *positron emission tomography* makes use of radioactive isotopes to observe the blood flow in the brain during cognitive tasks. Another technique, *X-ray computed tomography* (X-ray CT), relies on radiation and a contrast medium and, consequently, cannot be retaken many times. Apart from such neuroscientific apparatus, cognitive science also benefits from the tools used in psychological and sociological testing. Thus, surveys, questionnaires, and interviews may be applied in cognitive studies. As far as psychology software tools are concerned, one such program is E-Prime, aimed at testing one's response to the offered stimulus, such as reaction time. The selection of tools varies with the type of experiment. For example, research focused on quantitative methods relies on statistical tools. Linguistic methodologies may also be applied successfully in cognitive science. For example, the techniques characteristic of *critical discourse analysis* can be used to check the way a given message is understood and perceived by the target audience. Such linguistic analyses facilitate the understanding of the role of mass media in creating texts appropriate to the recipients' cognitive abilities and expectations.

Ethics and Future of Cognitive Science

It is important to note that conducting research in cognitive science also raises ethical issues with respect to experimental protocols when conducting experiments and data management. First of all, individuals taking part in experiments should be informed about the purpose of the study and the further application of acquired data. As far as the data itself is concerned, attention should be paid to the way it is gathered and stored.

The future of cognitive science depends on progress in other fields of study. For example, new methods created by linguists to investigate the ways in which people communicate may also determine advancements in cognitive studies. As in the case of other fields of investigation, technological advancements also shape the progress of cognitive science. Technology in that case should be analyzed from at least two perspectives. One of them is treating technology as the factor of development, offering new tools of creating, gathering, and disseminating knowledge. In that case, the newest technological achievements influence the level of sophistication characterizing the methods of investigating cognitive notions. For example, the development of such neuroscientific tools as fMRI or galvanic skin response offers a new way of studying human cognition. It can be envisaged that together with the development of neuroscientific tools, cognitive science will also offer new ways of understanding the way living entities behave. It can also be predicted that the interest in cognitive science will be intense within both medical and commercial domains. Thus, cognitive studies, together with accompanying disciplines, will become even more central in efforts to decode human behavior and its implications.

COMMUNICATION THEORY, TECHNICAL OVERVIEW

The terms *communication theory* (CT) and *information theory* (IT) are used interchangeably as synonyms in popular discourse. There are historical reasons for this that are easily explained. Also,

CT is often considered the modern derivation of *rhetoric*, dating back to Aristotle and Cicero. “Classical rhetoric,” however, is not the humanistic version of CT today, although *tropes of speech* are used as *logic models* for theory construction. CT currently refers to *communicology*, defined as the science of human communication using methodologies based upon the *normative logics* of human speech and gesture. CT is the *eidetic science of meaning* (semiotic signification, historically called *symbol theory* or *symbolology*). CT is a *binary analogue logic* that constitutes *certainly* (i.e., possibility differentiation) by combination judgments, simply formulated as a “choice of context.” CT is strictly formulated in logic as “the choice of a context by a relation which entails a choice by correlation” with the logic formalization: {Both [Both/And] And [Either/Or]}. Thus, CT explains a *message* that must express its own *code* simultaneously. Animals and machines cannot do this.

In simple terms, this logic formulation of communication as an *eidetic science* captures (*capta*) the basic facts of *human consciousness and comportment* (language) that operate at three code levels of consciousness unique to human beings. Human *codes* are (1) *synergistic* (qualitative rule: the whole is greater than the sum of the parts; Roman Jakobson's thesis that *metaphor* always dominates *metonymy*) and (2) *synesthetic* (quantitative rule: all human body senses are integrated simultaneously as one phenomenon; the thesis that *synecdoche* always dominates *simile/irony*) at three logical levels of expression and perception:

Affection or emotion. [pathos; *capta*]

Cognition or thought. [logos; *data*]

Conation or purposeful action. [*ethos*; *acta*]

The medieval philosophers use the respective shorthand terms *capta* (that which is *taken*; “awareness”), *data* (that which is *given*; “awareness of awareness”), and *acta* (that which is *done*; representation of awareness of awareness). Our contemporary terminology is *discovery*, *explanation*, and *explication* (or interpretation). The combined codes were *verba* (that which is *said*; *gērys* “communication tone”; see Figure 6).

By comparison, IT is the *empirical science of signal theory* (numerical algorithms) used in

electricity-based machines like computers, the name of which is *signal theory* or *informatics*. James Gleick offers a comprehensive social history of the information engineering concepts as they emerged in the United States in the 1950s up until the 1960s when, according to Gleick, in the social sciences, the direct influence of information theorists had passed its peak. Its specialized mathematics, he notes, has less and less to contribute to psychology and more and more to computer science.

Here, “psychology” (historically with Karl Bühler) is the example of the human sciences that advanced CT as prior to IT in theory construction. The critiques of Claude Shannon’s IT were made by Margaret Mead, Gregory Bateson, and Norbert Wiener (later by Jürgen Ruesch and Roman Jakobson) at the Macy Foundation Conference on Cybernetics held March 22–23, 1950, in New York City. Note that the “father of cybernetics,” Norbert Wiener, studied logic systems in 1914 at Göttingen University, Germany, with Edmund Husserl. IT is a *digital logic* that reduces uncertainty (i.e., constitutes *probability* differentiation) by exclusion judgments, simply formulated as a “Context of Choice.” IT is strictly formulated in logic as “the context of a choice by correlation which entails a context by relation” with the logic formalization: {Either [Either/Or] Or [Both/And]}. Machines are *spatially* limited to this logic, while animals are *temporally* limited by the logic. Thus, IT explains a *code* that must express a probability for all messages in the system (mechanical or biological).

In nonmathematical terms (“information” is an *algorithm*)—that is, in logical terms—the IT formulation gives (*data*) the basic quantitative procedure of *exclusion* whereby phenomena are negatively defined (*null hypothesis*) according to the presence [1] or absence [0] of an electrical signal in a digital system [0,1]. What is *not* the case [0] gives you a *probability guess* at what is the case [1]. If you can find one case to contradict the null hypothesis, then you have a correct judgment by probability. IT assumes a *closed system* (context) in which all choices are made. There are two important system facts here: (1) *Meaning* is not part of the theory and (2) the chosen message is *unknown*.

So, a machine or an animal organism is a closed system and probability of choice is *either* inside it or not. Which choice you make does not matter,

since either choice gives the same “information”; if, for example, you want a candy-bar from a machine, the machine signs reads “Insert \$1,” and you make a decision, or not, to insert a dollar. If you insert money, you may *either* get your candy or not [meaning is not in the system], the probability is the same; the only sure action is not to insert the dollar (not choosing the closed system). But you can take a chance by *both* inserting your dollar *and* hoping to get the candy bar [the message is uncertain]. IT always reduces the uncertainty of *how* you are choosing, but it never specifies *what* is chosen (either candy or no candy) among the possibilities! Machines are closed *spatial* systems; animals are closed *temporal* systems (information is limited to one generation). Digital systems (either/or = closed) can never operate *simultaneously* with analogue systems (both/and = open) because the digital operates at one logical level only. Only human beings can simultaneously operate an analogue of *three logical levels* by (1) simultaneously *both* remembering (2) what was chosen and not chosen [both/and] *and* (3) deciding which choice to act upon and which to ignore [either/or]. Remember that at stage (3), two choices are forever possible, even *after* a choice has been made. Humans call it “changing my mind,” that is, a “yes” and “no” becomes “maybe”!

Suffice it to say, much of the terminology confusion of CT and IT comes from the lack of careful research into stages of *theory construction* that emerged in 19th-century Europe, especially Germany where a distinction is drawn between the *human sciences* (*Geisteswissenschaften*), often called the “humanities” in the United States and the “eidetic sciences” in Europe, versus, the *natural* (physical) *sciences* (*Naturwissenschaften*). Keep in mind that in European history, all subjects studied systematically at the universities were “sciences” (especially literature) in contradistinction to theology and art. The same sort of name confusion is true for the 20th-century United States, where the distinction between “qualitative” and “quantitative” *methods* is equally confused by both sides of the debate over “two cultures” (human vs. nature), i.e., “sciences” versus the “humanities.”

To resolve these confusions, it is useful to review the standard framework for types of (1) *theory*, (2) *methods*, and (3) *models* (conditions of

Figure 1 Theory and Methodology Chart

Source: Lanigan (1992, p. 207).

interpretation for validity and reliability). Then, a brief review of historically significant *communication models* will help orient us, although it is necessary to show the humanistic correction in Claude Shannon's informatics model. Last, a summary table formulates the present combined heritage of the reviewed theories and models as they are in use today under the disciplinary names "communicology," "speech communication," and "discourse communication."

Theory and Model Construction

Theory is a set of propositions; in other words, statements expressing the complete normative criteria for choosing contexts of judgment constituting a set of *process rules* (Figure 1). Where a theory is applied methodologically to a specific subject matter, it is called a *model*. There are two basic ways to construct a theory. *Eidetic theories* use

human *thinking* as a conceptual or ideational process to make sense of, or be conscious of, a phenomenon that *can exist*. Such a phenomenon is a *realization* (it can be made into subject and object) or an *idealization* (no object is possible yet). According to the American logician and semiotician Charles S. Peirce, *eidetic theory* is either *analytical* or *critical*.

Analytic Theory

Analytic theory uses a *deductive logic* [Rule + Case = Result]. In the *same* context, [Rule] two phenomena [Case] are *internally* compared [Result]. This analysis requires *sufficiency* as a standard of judgment. *Sufficient condition* in *logic* means that you can find at least one example of the phenomenon, but the example can be a *mentifact* (real) or an *artifact* (actual). *Analytical models* of theory construction are *validity tested*

reflexively by *critical* models (an internal test) and by *experiential* models (an external test).

Keep in mind that two *different* “phenomena” may be the *same* phenomenon at different times/ places (Roman Jakobson’s logic of *distinctive* and *redundancy* features in CT). This is a key point in the study of discursive phenomena, especially with regard to Alfred Schutz’s temporal model of *interpersonal communication*: (1) *Predecessors* are persons who never share time/space, for example, you and your great-grandparents, (2) *consociates* (associates) are persons who do share time/space, e.g., you and your classmates, (3) *contemporaries* are persons who share time, but not space, e.g., you and the president of France, and (4) *successors* are persons who do not share time/space but can, such as you and your great-grandchildren. Another applied example is Margaret Mead’s model of *intergenerational communication as culture*: (1) *Postfigurative cultures* are those where children learn from their forebears [= Data], (2) *cofigurative cultures* where peers learn from peers [= Capta], and (3) *prefigurative cultures* where adults learn from children [= Acta]. All cultures progress through these stages as more and more generations combine their learning into a *logic of practice* [= Verba].

Using the logic of the philosopher Immanuel Kant, *analysis* is the division of a *whole into parts* (synecdoche) or a *substance into attributes* (metonymy); validity is tested by using the reverse process of critical *synthesis*. IT uses this logic (either/or choices) as a *reliability condition*.

Critical Theory

Critical theory uses an *adductive logic* [Rule + Result = Case (universal; *a priori*)]. In *different* contexts [Rule], an *external* comparison [Result] establishes the identity of two phenomena [Case]. Criticism requires *necessity* as a standard of judgment; that is, the eidetic claim that the comparison holds true in all *types* of the case (universal; no exceptions, all *tokens* fit all *types*) and that the *truth* of the claim (*tonality*) is obvious *before* it is experienced (*a priori*). *Necessary condition* in logic means the criterion by which the *realization* of one phenomenon (e.g., playing a *game*) is constituted, validated, and confirmed by the realization of *another* phenomenon (knowing or not

knowing the *rules* of the game). *Critical models* of theory construction are *validity tested* reflexively by *analytical* models (an internal test) and by *experimental* models (an external test). Again following Immanuel Kant, *synthesis* (criticism) is the addition of parts into a whole or attributes into a substance. CT uses this logic (both/and choices) as a *reliability condition*. In advanced theory construction (Figure 2), CT logic entails IT logic producing *metaphor* (substance/whole) and *simile/irony* (part/attribute). Note that this entailment is a strictly human capacity because *human consciousness* remembers *both* all choices made *and* all choice *not* made simultaneously. Machines (spatial limit) and animals (temporal limit) cannot do this; therefore, IT *never* entails CT; that is, a computer (or even group of computers) can be either digital (IT) or binary analogue (CT), but not both.

Empirical Theory

Likewise, according to Charles S. Peirce, *empirical theory* is either *experimental* or *experiential*.

Experimental Theory

Experimental theory uses an *inductive logic* [Case + Result = Rule]. With two phenomena [Case], an internal comparison [Result] establishes the same context [Rule]. Experimentation requires *actuality* as a standard of judgment. Actuality is the empirical presence/absence of a phenomenon, which validates the presence/absence of another phenomenon. An experiment requires *actuality as a function of probability* as a standard of judgment; that is, the empirical claim that the comparison holds true for this and subsequent cases (particular *tokens* and *types* cannot be distinguished) and that the truth claim (*tonality*) is dependent on the case(s) chosen. *Experimental models* of theory construction are *validity tested* reflexively by *experiential* models (an internal test) and by *critical* models (an external test). *Experimentation* is a function of IT: probability can make you more and more certain of *how* you are choosing, but it never tells you (defines) *what* you are choosing or have chosen. The usual example here is a *dictionary*: you look up the *signification* of a *word* only to be referred to other words that you

do not know. The dictionary is a *closed system*, which you already know, especially if you do not know how to *spell* the word (spelling is another closed system) for which you are searching.

Experiential Theory

Experiential theory uses *abductive logic* [Rule + Result = Case (particular; *a posteriori*). In the *same* context [Rule], an internal comparison [Result] establishes the identity of two phenomena [Case]. Experience requires *possibility* as a standard of judgment; that is, the empirical claim that the comparison holds true for this *type* of case (particular; all *tokens* fit the definition of *type*) and the *truth* of the claim (*tonality*) is obvious after it is experienced (*a posteriori*). *Experiential models* of theory construction are *validity tested* by *experimental* models (an internal test) and by *analytical* models (an external test). Experience is a function of CT; in other words, possibility can make you more and more certain of *what* you are choosing, but it never tells you (defines) *how* you are choosing or have chosen. The parallel example is an *encyclopedia*, where you look up the *meaning* of an *idea* that is fully explained by the entry. The encyclopedia is an *open system*, which you do not expect; there are more and more related *contextual* entries you can read (what you are doing right now!).

Method and Methodology

A *method* is a set of practices that are the actions a researcher uses to express the complete normative context (usually eidetic) for making choices among phenomena. *Methodology* is the creation of a *system* of methods for the constitution or production of *results* in logic. Where the context is limited (incomplete), it constitutes a *procedure*. Where there is only one known context, it is an *exemplar*. If you build a scaled physical version of the exemplar, it is called a *prototype*; for example, *writing* is a prototype of speech. All methodologies are *both quantitative and qualitative* as measure of space and time. For example, think of the verb tenses in the language you speak, the *grammar system* specifies space *quantities* (first, second, third, etc. person) and time *qualities* (present, past, future, gerund, etc.).

Quantitative methodology is the *practice* of using a *truth condition method* in order to compare and contrast choices made in a given context of magnitude, probability, or possibility. This is to say, all choices are true, false, or indeterminate (contingent). There are *three basic quantitative methods*: (1) *Mathematics* measures *magnitudes*; that is, differences by *degree*, such as a small versus a large, usually from a known or assumed reference point (a *foundation*) to a new point of reference (that which is “grounded”). Popular versions of this methodology are currently called “grounded theory,” although it is not a theory, but a mere *procedure*. In the human science context, the speech tropes of *metonymy* (substance and attribute comparison) and *synecdoche* (part/whole comparison) exemplify a *magnitude* measure in discourse. (2) *Statistics* measures *probability* (difference of kind and degree, e.g., two small vs. one large), usually from two assumed reference points (“dependent variable”) to two new points (“independent variable”) as a *correlation* (an either/or *disjunction*). A language example is the adjective system: “good, better, best”; such measures are often *not* logical, for example, “perfect, more perfect, most perfect.” The tropes of *simile* (positive part/attribute comparison) and *irony* (negative part/attribute comparison) exemplify a *probability* valence measure in discourse. (3) *Logics* measure *possibility* (difference by kind, e.g., an edible orange vs. a rotten apple), usually from a known or assumed reference point (a *class* or *type* such as “edible” or “rotten”) to a new point (that which is a *member* or *token* of a class such as “orange” or “apple”). The trope of *metaphor* (substance/whole comparison) is a discourse example of such a *relation* (a both/and *conjunction*).

Qualitative methodology is the practice of using a *necessary and/or sufficient condition* in order to compare and contrast choices made within a taken context of artifactual, symbolic, substantial, or formal *capta*. A *necessary condition* is a logical criterion by which the *realization* of one phenomenon is constituted, validated, and confirmed by the *realization* of another phenomenon; for example, in CT, any choice provides its own *context of meaning*; the choice is a necessary condition for the meaning. A *sufficient condition* is the logical criterion by which the *actualization* of one phenomenon is constituted, validated, and

confirmed by the *actualization* of another phenomenon; for example, in IT, either a “yes” or “no” choice provides the *same information*, or in other words, it affirms the *existence of the context*; each choice is a sufficient condition of the other choice.

There are four basic qualitative methodologies:

- (1) *Phenomenology* measures a narrative discourse as *true* by necessary condition (*apodeictic*) using formal capta (understanding) with a qualitative logic, rhetoric, or tropic of *foundation* (if/then logic). By tradition (*Ideographic Science* = “individualizing” judgment) in the discipline of *philosophy*, an *apodeictic* discourse is *critical*; therefore, validity is obtained in the application of an *analytical* review.
- (2) *Semiology* measures a narrative as *intuitive* by necessary condition (*problematic*) using substantial capta with a qualitative logic, rhetoric, or tropic of *relation* (both/and logic). Also by tradition (*nomothetic science* = “generalizing” judgment) in the discipline of *linguistics*, a *problematic* discourse is *experimental*; therefore, validity is obtained in the application of an *experiential* review. *Semiotics* is a synonym for “communication,” where communication includes the study of human, animal, and machine “languages” as icon, index, or symbol code systems.
- (3) *Ethnography* measures a *thematic* discourse using symbolic, mentifactual capta (knowledge) with a qualitative logic, rhetoric, or tropic of *correlation* (either/or logic). Traditionally (*Kulturwissenschaft* = cultural practice) in the discipline of *anthropology*, a thematic narrative is *experiential*; therefore, validity is obtained in the application of an *experimental* review. Ethnography is the systematic study of human cultures with particular attention to “space binding” relationships of a society (*Gesellschaft*) and culture (*Weltanschauung*).
- (4) *Historiography* measures an *assertoric* narrative (observation) using artifactual capta with a qualitative logic, rhetoric, or tropic of *correlation* (either/or logic). By tradition (*Geistgeschichte* = historiography) in the discipline of *history*, an *assertoric* discourse is *analytical*; therefore, validity is obtained in the application of a *critical* review. Historiography

is the systemic study of human cultures with particular attention to “time binding” relationships of an individual (*Lebenswelt*) and community (*Gemeinschaft*), for example, language, kinship, and ritual.

Communication Models: Karl Bühler

The first formal model of human communication was suggested by Karl Bühler in his 1934 book *Sprachtheorie* (Theory of Speech), where he depicts the semiotic process of human communication as an interpersonal interaction including the complex linguistic and psychological context. Bühler is correcting the semiotic phenomenology of Edmund Husserl and laying the procedural groundwork for Roman Jakobson’s later research using Russian poetry as a prototype. Unfortunately, the book was not translated into English until 1982; hence, it did not have much of an early influence in the United States, despite the fact that Bühler emigrated to the United States from Germany in 1940.

The model shown in Figure 3 depicts the acoustic phenomena of speech communication as a complex *sign* [s] symbolizing the *apperception* process by which the language sign displays the *apposition* of (1) a *symbol* of the objects and states of affairs or *representation* of the referent, (2) a *symptom* dependent as an index of the

Figure 3 Bühler Communication Model

sender or *subject of expression*, and (3) a verbal *signal* for the interpretation of the receiver or an *appeal* to the *addressee's* perception. All the parallel lines in the diagram illustrate the complex *semantic* functions at work in the creation of communicative *meaning*.

Communication Models: Claude Shannon

In 1948, Claude Shannon published a technical paper as part of his job at the Bell Telephone Laboratories entitled "A Mathematical Theory of Communication." The paper was of interest primarily to electrical engineers working on telephones and two-way radios, one of whom was Warren Weaver. Weaver wrote a popular explanation of the theory for the magazine *Scientific American* in 1949. In the article and subsequent reprints, he argued quite *incorrectly* that the

general model depicted in Figure 4 could be generalized from *closed* machine systems to human communication as an *open* system. Unfortunately, Weaver had no knowledge of logic or linguistics and was not at the Macy Conference in 1950 where his errors were corrected. His unjustified generalization started a confusion that is still with us today in which IT (Signal Theory and Informatics) is confused with CT (Symbol Theory, Linguistics, and Rhetoric). Fortunately, Shannon corrected Weaver by noting that for *human communication symbols* using an electrical machine, the process shown in Figure 5 would be necessary. Here, a human observer using human *language* is always part of the construction and corrective maintenance of the communication *process*. There are two important IT facts here: (1) *Meaning* is not part of the theory and (2) the chosen message is *unknown*. Keep in mind as well that Shannon's

Figure 4 Shannon Signal Model of Informatics

Figure 5 Shannon Observer Model of Informatics

model is *linear* (one-dimension, directional action with control = cybernetics) and does not account for the complexity of *curvilinear* human interaction (three dimension, multidirectional transaction = semiotics).

Communication Models: Ruesch and Bateson

As an immediate correction of the IT and CT confusion, Jürgen Ruesch and Gregory Bateson published their historic book *Communication* in 1951. The volume immediately set down the conditions for a “human observer” model of communication (Figure 6). Note in fact that this book sets the basic divisions for research and teaching that

have become the main areas of the *human communication discipline*: (1) intrapersonal communication, (2) interpersonal communication, (3) group communication, and (4) cultural communication. As Ruesch and Bateson (2008) specify, “The focus of the human observer is not fixed; rather it has to be viewed as a fluctuating or oscillating phenomenon in which quick glances are taken rapidly at various levels and at various functions. Communication is an extremely dynamic phenomenon with a rapid rate of change of levels and functions, which range from evaluation to transmission and conduction” (p. 274).

The famous “Table D” from this book defined the research agenda of the discipline (note that

JÜRGEN RUESCH AND GREGORY BATESON DISCOURSE OBSERVER MODEL OF COMMUNICOLOGY (1951)

Handchart © 2019, Richard L. Lanigan, Ph. D.

THE LEVELS OF COMMUNICATION

Figure 6 Ruesch and Bateson Observer Model of Communication

Table 1 summarizes an updated version). We need to recognize that Jürgen Ruesch is the virtual founder of the modern human science discipline of communicology with his collected work appearing in *Semiotic Approaches to Human Relations* (1972) and his *Knowledge in Action* (1975), which is the foundational research devoted to “communication, social operations, and management.”

Communication Models: Roman Jakobson

By 1958, CT was fully integrated with linguistics and semiotics, and Karl Bühler’s work was emerging indirectly in that of Roman Jakobson. A linguist who wrote in eight languages, Jakobson conceives of communication as the unifying theory that connects all the levels of the human sciences, both in theory and methodology. His

Figure 7 Roman Jakobson Human Sciences Model

Figure 8 Roman Jakobson Model of Communication

Key to symbolic notation: E_1 = The Background Experience and Attitude of the Communicator; CC_1 = The Concept of the Communicator; S_1 = The Symbol(s) Used by the Communicator; R_1 = The Referent(s) as Perceived or Imagined by the Communicator; S_2 = The Symbol(s) as Understood by the Communicatee; R_2 = The Referent(s) as Perceived or Imagined by the Communicatee; CC_2 = The Concept of the Communicatee; E_2 = The Background Experience and Attitude of the Communicatee; Tr = The Transmitting Device, Mechanism, Medium of Expression; Rc = The Receiving Device, Mechanism, Medium of Perception; ? = The Mediation Possibility of a Relationship as Response (Verbal), Reaction (Nonverbal); a—i = Specific Boundary Relationships That Are Necessary (validity) and Sufficient (reliability) Conditions in the Communicological Process

human science model is illustrated in Figure 7 along with the basic definitions of the hierarchy of development among the various eidetic and empirical science disciplines. He begins with *linguistics* as foundational moving logically outward to develop the general communication systems of all organic life forms.

Jakobson goes on to specify his model of human communication, as shown in Figure 8. The model consists of six *elements* of the communication process with six corresponding *functions* of transaction. While the model is illustrated in the procedural terms of dyadic interpersonal communication, it is critical to understand that the dyadic process can apply at *all four levels* of the Ruesch and Bateson model. This is to say, the model explicates all communicative levels from intrapersonal (e.g., one's own thinking) to interpersonal (e.g., conversation), to group (e.g., a work team), and to cultural (e.g., a global conference).

Communication Models: Hubert Griggs Alexander

By 1967, CT became a focal point in the discipline of *philosophy*, which today flourishes as the “philosophy of communication” in most of the

professional associations worldwide. As a student of Ernst Cassirer, Edward Sapir, and Wilbur Marshall Urban at Yale University, Hubert Griggs Alexander's work is the original classic contribution to explicating the *philosophic* concern with how human thinking operates as *rationality* through the interactive agency of language and logic. Figure 9 reproduces Alexander's model along with some insertions [in brackets] to show the correlation with Roman Jakobson's model.

While this model is a *prototype formalization* of the communication process, its simplicity in specifying the elements, functions, and stages of the process is a masterpiece of *procedural description*. Using the model allows a comprehensive description of each aspect of the *encoding* and *decoding* processes that govern communicative and semiotic *competence*. The model is most useful from the point of view that communication *failure points* can be located and described with great precision, that is, points at which *performance* misunderstanding displaces understanding. For ease of use, these process functions are presented in outline form. Outline lettering (a, b, c, etc.) corresponds to model lettering in Figure 9. Each example is a *prototype* of actual communication practice.

Table 1 Communication Theory Table of Elements, Functions, and Levels

❶ Failures in Conceiving and Encoding

(Signification = Language System; Message-to-Code).

- (a) **Referent:** Epistemic-Pragmatic Failure from forming the wrong idea by the Communicator may be due to:
 - [1] Unclear Perceptions (e.g., mistaking a “cat” for a “dog”).
 - [2] Improper Conceptualizing (e.g., mistaking a cardinal [“1”] for an ordinal [“first”] number).
 - [3] Wrong Application of a Properly Conceived Idea (e.g., taking Earth to be a perfect sphere).

- (b) **Experience:** Epistemic-Emotive Failure because of Preconceptions on the part of the Communicator may be due to:
 - [1] Lack of Appropriate Background Experience.
 - [2] Inadequate Education.

- (c) **Symbol:** Semiotic-Semantic Failure in Encoding (Using the Wrong Symbols) may be due to:
 - [1] Inadequate Knowledge of the Symbol System (e.g., saying “dog” when one means “cat”).
 - [2] Using Ambiguous Symbols, or Symbols that are apt to be unfamiliar to the Communicatee, either intentionally (deception) or not (mistake).

❷ Failures Due to Expression (Transmitting) and Perception (Receiving).

- (d) Physiological Failures of the Communicator (e.g., mis-articulation, stuttering).
- (e) Mechanical Failures in Transmitting and Receiving (e.g., mispronunciation, noise).
- (f) Physiological Failures of the Communicatee (e.g., being hard of hearing, unfamiliar accent).

❸ Failures in Decoding and Discovering the Correct Referent (Meaning = Speech System; Code-to-Message).

- (g) **Symbol:** Semiotic-Semantic Failure in Decoding (Using the Wrong Concept from the Symbols Received) may be due to:
 - [1] Inadequate Knowledge of the Symbol System Used by the Communicator (e.g., hearing a foreign or unfamiliar language).
 - [2] Not Recognizing All of the Implications of the Symbols Used (e.g., not detecting irony in the speaker’s tone of voice).

- (h) **Experience:** Epistemic-Emotive Failure because of Preconceptions on the Part of the Communicatee (e.g., having a misconception of geographical orientation, which leads to a failure to understand directions; or, having no experience with an object which is being described to one).
- (i) **Referent:** Epistemic-Pragmatic Failure in Finding the Correct Referent (e.g., failure to get from the correct, but too general, concept to a specific referent)

Communicology: Human CT

CT as a human science represents one example of complexity in theory construction with attendant methodological concerns. Figure 9 allows a comprehensive synthesis of many of the content and structural relationship issues that exist in the *discipline of communicology*. However, it is essential to remind ourselves that theory and methodology are options that may be combined, and are, to solve particular research problems. The key to understanding the “humanistic” influence on communication is that the correct name is *human science* and that *science* uses rules of validity and reliability that must be specified when research result claims are made. Historically, *human science* relies on *logic* to make eidetic and empirical claims. By comparison, the *physical sciences* rely on *mathematics or statistics* to make similar claims. The concepts (terms) of *eidetic* (human consciousness) and *empirical* (human experience) are badly misused by most people who have not been trained in theory construction in their particular discipline, largely because the *practice* of most research is driven by habitual *procedures* of unquestioned methodology. Table 1 *categorizes* the issues of *theory construction* that explicate and explain human beings communicating with human beings. Methodology is not illustrated because it is a secondary concern, since all methodologies are used by all disciplines in both the human and physical sciences.

COMPLEMENTARY MEDICINE

Complementary medicine is the provision of traditional remedies in concert with conventional, Western-based, scientifically informed medicine. Each type of practitioner may provide treatment in the form of substances to be consumed or applied to the body in some way or therapies to be enacted on the body or mind. However, in the case of traditional medicine, typically, the herbal remedies or behavioral modifications suggested by healers have not been tested rigorously by controlled clinical trials, investigating outcomes and risks. Instead, the practices are supported by beliefs, personal accounts, and hopefulness. This entry describes the origins and nature of complementary medicine, with particular emphasis on current practice in the United States.

The strong role of customary beliefs in traditional medicine and the variety of cultures around the world have resulted in many different traditional practices being included in the category of complementary medicine, with no overarching philosophy connecting these disparate treatment regimes. For example, among the Dogon, in southern Mali, childhood illness may well be regarded as the effect of witchcraft, supported by local cosmological understandings of the world, and treated with culturally specific substances and behaviors. These Dogon healing practices are different from those found among Maya Q'eqchi', in rural Guatemala, where there may be similar local reactions to childhood illness, but interpreted according to Q'eqchi' beliefs, and with different treatment protocols. In traditional medicine, there is no overarching system incorporating these diverse healing methods, as is the case with mainstream medical understanding, based on the scientific testing of theories, with ongoing evidence-based treatment improvements.

In addition to lacking scientific verification, traditional healing is characteristically more

broadly focused than the conventional medical concentration, which typically deals only with the body or the mind. Healers may also incorporate a spiritual element, often accompanied by attention to the patient's relationships with others, such as the family or the community or even the environment. This means that curing events may be viewed as religious ceremonies and may also involve the members of the extended family, sometimes accruing considerable financial cost and organizational challenge.

Traditional healers usually are not medical school graduates but instead have learned their techniques from other traditionalists. Curers provide their treatments in villages and towns around the world, especially in less-developed nations, where traditional belief systems are supported, such as Nigeria, Cambodia, or Guatemala, and increasingly in large cities with immigrant populations, in developed nations such as the United States and Canada.

In North America, many minority community members use their cultural healing practices in combination with mainstream, Western-based medicine. A smaller group of people rely solely on traditional medicine, and in these cases, individuals are employing alternative medicine rather than complementary medicine. People may shift between these strategies at different life stages, depending on their conceptualization of health, their understanding of the practices, and the type of ailment experienced.

In addition to shifts in individuals' use of health therapies throughout their lives, there are also advances in medical knowledge, which mean that the boundary between acceptable and unacceptable healing practices is in flux. Indeed, many formerly traditional practices are now accepted as standard medical techniques, such as the use of massage, which is now often combined with exercise at physiotherapy clinics treating back injuries.

Sometimes, people access complementary medicine by requesting referrals from their mainstream medical provider. This might be the case for back injuries, when a family doctor may suggest visiting a chiropractor. This type of referral may be covered by some types of health insurance.

At other times, people find complementary medicine through their own networks and may

begin activities such as meditation or consuming products such as megavitamins or herbal mixtures, based on recommendations from friends, local community members, internet reviews, or other sources. Some of these individuals may consult their medical doctor when deciding to try these treatments, while others just use their own judgment. In most of these cases, the complementary medicine accessed would not be covered by health insurance. Regardless of whether people have health insurance coverage, a wide variety of complementary medicine types are available in the United States.

Types of Complementary Medicine in the United States

The first Americans, namely, American Indians and Alaska Natives, lived very different lives, spoke very different languages, and had very different traditional medicines, one from another. Different tribal groups inhabited dissimilar regions, each with distinctive flora and fauna, which could be harvested and used for curing. Occasional accounts of aboriginal treatments were recorded in early histories. For example, in 1535, Jacques Cartier, while exploring what is present-day Quebec province, Canada, encouraged his sailors suffering from scurvy to consume an Iroquoian drink based on boiled coniferous needles, which contain ascorbic acid and which cured the underlying vitamin deficiency.

Despite a few early positive interactions between explorers and American Indians, with ongoing European contact and settlement, many aboriginal groups were separated from their land and lost their knowledge of local plants, the basis of customary healing lore. Although much has vanished, some groups have managed to retain traditional knowledge, and it is typically available to indigenous people through healers, some of whom may be found at health clinics or through community providers. Another source of traditional knowledge is through American Indian doctors working in clinics, who have reconnected with cultural beliefs to incorporate these in a complementary fashion in their contemporary medical practices. This was the case for Dr. Lori Arviso Alvord, who received her medical degree from Stanford University, becoming the first

surgical board–certified Navajo woman in 1994. Dr. Alvord works holistically with her Navajo patients, providing a Western medicine–based practice, incorporating traditional beliefs about balance and relationships, described in her book, *The Scalpel and the Silver Bear*.

Balance in individuals, families, and the world is important in Navajo cultural cosmology. Transition periods, or other times of imbalance, are treated through curing ceremonies involving chants, sand paintings, food, and other ritual activities to restore stability. People who have grown up in the remote reaches of Navajo Nation feel validated to visit a doctor who understands their foundational beliefs. However, this type of complementary practice remains atypical for American Indians and Alaska Natives because there is a paucity of indigenous doctors graduating from medical schools.

In recent history, Native American populations have been outnumbered by newer residents. Each of these different immigrant groups has imported their own beliefs and ideas about health, illness, and treatment to the United States. For example, in the 19th century, Chinese herbal shops were located in many urban centers in California and were heavily utilized by local Chinatown residents. At the time, outsiders did not typically frequent these shops, given the high levels of discrimination against Chinese immigrants. More recently, with improved ties between China and the United States and decreased stereotyping of the California communities, some traditional practices, such as acupuncture, have increased in popularity, becoming well known among the users of complementary medicine.

Even more widely accepted than acupuncture is yoga, which is originated in ancient India. This practice involves moving the body into named poses (*asanas*), often involving stretching, strength, and balance, and is often provided to groups of people at yoga studios, led by a single expert practitioner. Some studios also incorporate chants and a spiritual focus to the practice, publicizing traditional Indian ideas about the body and health. Yoga attendees attend classes for a variety of reasons, ranging from appreciation for the body benefits of the stretching routines to a desire for fuller immersion in Indian belief systems, sometimes including visits to India.

Healthful practices are one type of complementary medicine, and the other broad category is consumable products. In the United States, practices would include the aforementioned acupuncture and yoga, in addition to massage, meditation, movement therapies, and relaxation techniques, among others. Consumable products include herbs and supplements, often for consumption but also for skin or other applications. Given all these types of available complementary medicine, the following section investigates the prevalence of these treatments among U.S. Americans, and some current trends.

Prevalence of Complementary Medicine in the United States

It is difficult to determine how many U.S. residents use complementary and alternative medicine, since there are differences in how studies use and define the terms. Researchers may ask people about holistic medicine or use the phrases unorthodox, unconventional, or marginal, which may be more or less inclusive of different treatments. For example, considerations of Navajo ceremonies typically incorporate the use of prayer as part of the treatment. In the case of Mexican curing ceremonies, should prayer also be included or is this something separate from medical treatment? These issues make it difficult to compare different studies and to consider rates of change in complementary medicine uptake or regional differences.

Notwithstanding, there are some surveys that have used terminology consistently and which provide several years of administration; these are particularly helpful for examining trends. A good example of a useful U.S. survey is the National Health Interview Survey (NHIS), organized by the National Center for Health Statistics, included in the Centers for Disease Control and Prevention. The study was initiated by the U.S. National Health Survey Act of 1956, and the first cross-sectional household-based survey occurred in 1957, with yearly iterations, although in 2019, the format was changed. Until 2018, it was based on questions formulated in 1997, and in 2002, 2007, and 2012, a subset of questions asked about complementary medicine. In 2007, the questionnaire was supplemented by interviews about

complementary medicine use by adults, included their reasons for usage.

The NHIS results for 2002 show complementary and alternative health usage by approximately 36% of U.S. American adults. Five years later, 38% of adults and 12% of children were accessing these treatments, and adults were spending US\$33.9 billion to fund products and practices. The most popular practice was deep breathing, with approximately 13% of the sample following this trend, followed by meditation, chiropractic, osteopathic treatments, massage, and finally, yoga, completing the more supported therapies, with approximately 6% of adults following this regimen.

In the same year, approximately 18% of these adults consumed herbal supplements. A 2012 estimate of the size of the nutritional supplements market worldwide suggests US\$32 billion in earnings, with extensive use of social media to reach consumers. As a result, many items that were once purchased only by intensive body-building competitors and marathon runners are now found on the shelves of typical households, and even children regularly consume energy drinks and bars.

The increase in family usage of complementary medicine correlates with a decrease in child vaccination levels. This effect has been identified in various studies, such as articles in the *American Journal of Public Health*, *Pediatrics*, and *Public Health Reports*. Each of these studies cites additional research documenting similar trends. As a result, different medical and health institutions try to deal with the low vaccination levels in various ways.

Many schools do not allow student registration unless vaccination schedules are completed, although increasing numbers of parents apply for vaccine exemptions, and nonvaccination rates are increasing, as shown in online links in Hill and colleagues' article in the *Morbidity and Mortality Weekly Report* and other links on the Centers for Disease Control and Prevention website. This trend is also reflected in universities recording many students without vaccinations in campus dormitories. These decreasing levels of vaccination compliance are accompanied by the spread of childhood diseases that were considered to be almost eradicated in the United States only a few years ago.

Several additional patterns have been identified in the use of complementary medicine. Generally, people who access conventional medical services at higher levels also tend to access alternative treatments with greater frequency. It also seems likely that people who use both types of service will attempt to source both when suffering a medical crisis and will then utilize whichever first becomes available. However, sometimes, people will turn more frequently to treatment with lower scientific support if they face too many barriers in sourcing standard medical services. These barriers may range from negative experiences with hospital outpatient procedures to denial of insurance coverage or other events, which may sour their views of conventional U.S. American medical provision.

Research also demonstrates that complementary medicine is applied in new and unusual ways, although it is difficult to document these trends unless the right questions are asked. For example, a 2008 study conducted by Jon C. Tilburt and colleagues, published in the *BMJ*, demonstrated that approximately half of 679 sampled internists and rheumatologists prescribed treatments that might be helpful for patients, although lacking in scientific proof of benefits. The analysis concluded that in these situations of long-term degenerative illness, physicians hoped to harness patient expectations in a placebo-like response. This unanticipated outcome in how doctors consider and apply complementary medicine hints that other unexpected results may occur in the future, given increasing efforts to bring complementary medicine into the fold of mainstream medicine through clinical tests of practice and treatment outcomes.

Contemporary Application of the Scientific Method to Complementary Medicine

Given the long-term usage of traditional medical practices and remedies and the increasing popularity of this style of medical provision in the developed world, it makes sense to evaluate the treatments, with the goal of diminishing the use of harmful practices and increasing understanding of beneficial ones. Perhaps, the best way of achieving this goal is to fund scientific studies, with controlled variables, random placement of research

participants into treatment and placebo groups, and accurate recording and publishing of results. There are many challenges in incorporating this strategy worldwide, but among the possible starting places may be the World Health Organization providing support for incorporating some aspects of traditional medicine into mainstream medical interventions. This offers an important way to supplement the inadequate number of trained medical doctors in many regions of the world and also a beginning in better documentation of local treatments utilized, with the aim of improving both mainstream health provision and complementary services.

In the United States, the U.S. Department of Health and Human Services established in 1998 a new National Institute of Health unit, the recently renamed National Center for Complementary and Integrative Health (NCCIH). As of fiscal year 2020, this unit controls approximately US\$151.9 million in funding and has supported numerous scientific investigations of products and practices with clearly documented results disseminated through academic publications and available to the general public online. The end result is improved public safety.

Some of the publicized research focuses on increasing awareness of beneficial practices for certain medical conditions. For example, in 2009, a study appeared in the academic periodical *Spine*, and also a simplified summary was placed online for general consumption. The investigation documented the value of Iyengar yoga for people with low back pain, decreasing pain levels, and improving body function and mood. In this manner, studies move complementary medical practices into the mainstream medical arena.

Other NCCIH-supported research focuses on diminishing harm, such as warnings about toxic materials in supplements. For example, a study conducted in 2005 and reported in 2008 in the *Journal of the American Medical Association* documented high levels of lead, mercury, and arsenic in a sample of Ayurvedic medicine purchased over the internet from Indian and American suppliers. Approximately one in five of the 193 tested products contained toxic metals, including those sourced from businesses extolling the benefits of their product testing. This type of information is extremely useful for those who order these products online.

In the future, it is likely that continued scientific testing of complementary medicine will result in better medical provision not only in North America but elsewhere, as well as a more efficient medical system, satisfying people from a variety of cultural backgrounds, with different conceptions of health and illness. This process will only be improved by increasing the numbers of minority graduates from mainstream medical schools.

COMPLETENESS

Completeness is a property that theories can have when treated using the tools of modern mathematical logic and its mathematically precise treatment of logical consequence. This entry discusses two senses in which theories may be complete. Given the idealized view of theories logic employs, completeness in one sense has only been studied in relation to mathematical theories. But there is also a sense of completeness that applies to a theory of logical consequence, it is the completeness of a deductive system of logic.

Theories are a form of knowledge in which core concepts and assumptions are systematized so as to organize the understanding of the theory’s subject matter. The composition of theories in science can be very complicated. They may consist of data, experiments, models, and even research programs; they are not expressed in a uniform way. However, in logic theories are treated in an idealized and uniform way: All theories consist only of statements. Insofar as we can paraphrase the core elements of a theory into statements, this idealization is not misguided. Thinking of theories in these terms can help organize and reduce the number of core elements of a subject, since many other facts about the subject matter will follow directly from those core concepts. Logic studies a particular way that consequences can be drawn from statements, namely logical consequence.

Statements are related by logical consequence when one statement follows from a set of statements with certainty. For example, the Law of Gravitation predicts the velocity at which a stone hits the ground when it falls from a cliff. This is an elementary instance of one statement about a particular stone’s velocity following, with certainty, from a general statement together with other statements about the particular height of the cliff.

Background on Logic and Consequence

There are two distinct notions of completeness: one that applies to theories, and one that applies to a deductive system of logic. In order to understand either of these ideas, the concepts of a logical language and logical consequence must be clear.

A logical language is a recursively defined set of sentences that are built up from atomic components using logical connectives. Logical languages may be defined so that they allow the use of particular connectives or names for particular objects, and the introduction of particular predicates or multi-place relations. These are languages that can easily be adapted to describe applications of logic to the empirical world. The logical language of sentential logic (SL), also called *propositional logic* or *truth-functional logic*, uses simple sentence atoms as basic units and introduces special symbols for the words *and*, *not*, and others. First-order or predicate logic uses names, variables, and multi-place relations to form basic sentence atoms and adds to the symbols from SL symbols for *all* and *some*. Some languages might adopt a particular predicate, for example, $x < y$, as well as a particular range for its variables, for example, the positive integers.

The logical language defines sentences syntactically, and they may have a formal or an informal interpretation or meaning. The relation of *logical consequence* is a relation between sentences of a logical language, some defined as the premises and others as the conclusion. The premises of an argument may deductively prove one or more conclusions. The consequences of the premises are what *follows from* the premises.

As a result of the foundational work of Gottlob Frege in 1893, modern logic thinks of logical

consequence in two possible ways. The first is logical entailment, and the other is deductive proof.

Entailment

An *entailment* is a semantic (a truth and/or meaning based) relationship between a set of premises and a conclusion. Different semantic systems may be considered in philosophical or mathematical logic, but the classical relationship (which makes the common assumption that every sentence is either true or false and not both) of entailment is that the truth of the premises guarantees the truth of the conclusion. This is the standard definition of deductive validity. A distinct intuitionistic notion of entailment would result from eliminating the assumption that every sentence is true or false, construing true as “demonstrated or proved” and false as “refuted or disproven.” Entailment is understood in relation to assumptions about truth, and in relation to interpretations that make atomic sentences true. Classical logic uses classical interpretations, and intuitionistic logic uses distinct interpretations. To make things more general, let us represent the premises by a set of sentences, which we indicate with the symbol Γ and the conclusion by the letter φ . We then introduce the meaning of “ Γ entails φ ” in the following way:

$$\Gamma \models \varphi$$

if and only if every interpretation that makes all the members of Γ true, also makes φ true.

It would be possible to add subscripts to $\models$ if we needed to distinguish between different senses of entailment.

Deductive Proof

Logical consequence can also be understood as a relation determined by proofs. Proofs given in natural language, like those in mathematical research, are arguments which follow a set of rules and (may) use axioms to represent some fundamental facts about the subject matter of the argument. Proofs in formal logic are intended to carry out that project in such a way that the set of rules used in constructing the proof rely wholly on the symbols used in representing the premises and conclusion of the argument. In this way, formal

proofs are meant to capture the idea that the proof relation of an argument is based only on the form of the sentences (their syntax), and the logical words used, and not on their meaning or content. Such a system of proof avoids semantic intuitions about the meanings of the symbols and keeps unstated premises or *intuitions* from entering into the proof.

Relative to a language L , there are many methods that can be used to show that a set of sentences Γ can prove a sentence φ . These are so-called proof theories or deductive systems. Some systems represent proofs in a series of sentences each of which is either an axiom of the proof theory—a sentence which is taken for granted—or is derived from previous sentences in the series by rules which operate on their syntax. These are known as *Hilbert-style proof theories*. Other deductive systems do not use axioms; those systems have rules for the introduction of assumptions, and other rules which operate on the symbols of sentences derived from those assumptions or allow one to eliminate assumptions. These are known as *natural deduction systems* since they are meant to mimic the structure of proving things in natural mathematical contexts. There are other systems like so-called sequent systems or proof trees, but all of these create a rule-governed syntactic method to determine when φ is proved from a (possibly empty) set of sentences, Γ .

Regardless of its kind, once one has a system of deductive proof, LS , operating on a formal language L , it gives rise to a syntactic relation of logical consequence. We say that:

$$\Gamma \vdash_{LS} \varphi$$

if and only if there exists a proof of φ from Γ according to the rules of LS .

Theory Completeness

In mathematical logic, once one has fixed a logical language L , the theories in that logic are sets of sentences of L that contains all of their own logical consequences. In the terminology from above,

Γ is a *theory* in L relative to a notion of logical consequence $\models$

if and only if φ is a member of Γ when $\Gamma \models \varphi$.

When logicians speak of the theory of Peano arithmetic, for example, they mean the axioms of Peano arithmetic taken together with all of the logical consequences of those axioms. This notion can apply to theories in general, if we understand theories as collections of statements.

A theory Γ is *complete* when for each sentence φ of L , either $\Gamma \models \varphi$ or $\Gamma \models \neg\varphi$.

That means for each sentence φ either φ is entailed by the theory or φ is refuted by the theory. It is important to note that this notion of completeness is restricted to L , so although a complete theory will pass judgment definitively on each sentence, the content of those sentences will be restricted to whatever L can express. Complete theories tend to be fairly limited in complexity.

The theory of Presburger arithmetic is a complete theory, but it is an arithmetic that only deals with addition on the nonnegative integers: it cannot represent multiplication. And if multiplication were added to this theory, that could start to cause problems. One of the major results in logic is Gödel's Incompleteness Theorem of 1931. What Gödel proved was that if PA (Peano arithmetic qua theory) is consistent, then it is incomplete. So, provided PA is consistent, there are sentences φ in the language of PA such that neither $PA \models \varphi$ nor $PA \models \neg\varphi$. And PA is very nearly Presburger arithmetic with multiplication added.

The notion of the decidability of a theory or a logical system is different from the completeness of a theory or a logical system. A theory is decidable if and only if there is an algorithm that is usable in a finite time to determine whether an arbitrary sentence of L is a member of a theory or not. Whereas the completeness of a theory is about what sentences are entailed by the theory, the theory is decidable when given an arbitrary sentence, φ one can determine whether φ is entailed or refuted by the theory.

Completeness of a Logical System

The other sense of completeness is one that applies to logical systems. Recall the idea of deductive proof from above. A logical system's proof theory is complete when the proof theory relation $\vdash$ and

its entailment relation $\models$ are extensionally equivalent. That is, for all of the pairs of sentences or formulas Γ, φ in L ,

$$\Gamma \vdash \varphi \text{ if and only if } \Gamma \models \varphi.$$

When logicians prove completeness theorems or logicians say that a logic is complete, this is what is meant. A version of this result for first-order predicate logics was first proved by Kurt Gödel in 1930; that theorem is often referred to as *Gödel's Completeness Theorem*.

Strictly speaking, however, calling a logical system *complete* is an abuse of terminology. The completeness of a logical system is really about the proof theory exhausting the entailment relation of the system: if $\Gamma \models \varphi$ then $\Gamma \vdash \varphi$. The proof theory will not miss out on any of the valid arguments that the entailment relation says are valid. The other direction, if $\Gamma \vdash \varphi$ then $\Gamma \models \varphi$ is called the *soundness* of the proof theory. That means the proof theory will not lead one astray; all of the conclusions one can draw from Γ using the proof theory are entailed by Γ . It is very important to note that these notions of completeness only apply *relative* to a particular theory of consequence. It is the completeness of the proof theory with respect to a particular entailment relation or semantics for the language L . The completeness of a logical system says nothing, on its own, about the system's adequacy as a theory of valid argument.

There are many theories of entailment which reject central assumptions of classical predicate logic. For example, some logical theories relax the assumption that sentences may only be true or false. Some theories allow sentences to take on other truth values (many-valued logics) or even allow there to be sentences which are both true and false (paraconsistent logics). These semantic theories give rise to substantially different entailment relations over the same language as classical predicate logic. What is interesting is the proof theory for classical predicate logic is not incomplete with respect to these other entailment relations. The proof theory tends to be *unsound* with respect to those entailment relations. What the logician then does is devise new proof theories which are sound for the new notion of entailment/semantics.

COMPLEX SYSTEMS

Complex systems theory, sometimes referred to as *complexity theory*, does not originate from a single discipline and hence does not have a singular definition. In order to approach a useful theory of complex systems, we can identify shared definitions and typically attributed qualities in order to attain an overview, if not quite a consensus. This entry provides a working definition of a complex system, describes the structure of systems generally, and goes on to identify and explain the core concepts inherent in the study of complex systems and the theories that have been advanced by scholars in the various disciplines from which this field emerged. The entry concludes with a detailed discussion of the most widely recognized theoretical influences and movements related to and coming out of the study of complex systems.

A complex system is made of multiple components, which interact with each other over time, resulting in patterns of behavior at the system level and at other scales that cannot be predicted through a simple causal understanding of the individual parts and their functions. Furthermore, the organization of components and the relationships of parts to each other at individual and collective scales in terms of flows and interactions are as important as the components themselves for cognition of system behavior. In other words, typically reductive

approaches that are used to break down “complicated” problems into smaller parts, which are resolved separately, are unlikely to produce results in the study of complex systems or to unveil traceable causal chains resulting in collective dynamics.

Although this is an extremely generalized description, it will be expanded in order to demonstrate how this statement incorporates possibilities of emergent behaviors, self-organization, unpredictability, feedback loops, and sensitivity to initial conditions and in some cases outcomes based on learning, memory, and interaction with environments, similar to evolution. There is a clear distinction between “complex” systems and “complicated” systems. A number of extremely complicated systems exist, such as airplanes and large infrastructure projects such as dams. The aim and characteristics of these complicated systems are that they are predictable and linear: The same outcome is always expected for the same input, with any deviations from this treated as errors to be corrected. Complex systems, on the other hand, are typically nonlinear, and while it may be possible to identify the patterns of behavior, the system is not predictable in all aspects.

Many real-world systems demonstrate some or all behaviors attributed to complex systems. Examples include ant colonies, the biosphere and ecosystem, the immune system, social or political groups, the global economy, and cities as both artifacts and living adaptive systems. Theories from complex systems have gained popularity over the past few decades, partially due to the failure of existing theories to explain or predict real-world phenomena such as the global financial crisis of 2007–2008. They are also providing useful approaches to function and learn across different disciplines, such as physics, biology, economics, ecology, mathematics, computation, and economics, through identification of similar or overlapping phenomena. Complex systems theory emphasizes the impossibility of a single perspective or language to describe all the qualities of the system or a single entity to control all aspects of the system. It creates the need to reconsider the logic of reductionism, the absolutes of positivism, and the causality of determinism. While frames of reference and subjectivity from relativism are part of complex systems, lack of validity intrinsic to absolute relativism is not accepted as the default outcome. Instead,

systems of relations between objects, as acknowledged in G. F. W. Leibniz's relationist description of space and time and Joseph Kaipayil's reference to relational particulars, appear to provide a more useful operating framework.

The System in Complex Systems

A system can be described as a structure comprised of components or a group of elements that are interactive and/or interdependent and hence related to each other in some way. The components of a system have also been identified as entities, parts, or members depending on the context of use. Some descriptions of systems are based on the maintenance of functionality toward a goal, but in the context of complex systems, a singular or specific "goal" can be contested and interpreted. Examples of physical systems typically refer to assemblages of things and parts making up a whole, such as a railway system. If things are replaced with facts or principles, then the assemblage can be described as forming a system of thought or knowledge. A coordinated collection of steps or methods may form a system of organization. The definition of a system typically necessitates the possibility of differentiating it from other systems, even while acknowledging that systems can influence, overlap with, be contained in, and contain other systems. A currency such as the Euro is an identifiable system that is subject to the rules of international monetary systems and influenced in terms of value by trading between nations in foreign exchange markets. System boundaries can be defined by the system observer.

Systems typically demonstrate a degree of robustness. The idea of robustness is contestable due to disciplinary interpretations, but in a general sense, a system that can still be identified using the initial criteria in the face of changing external conditions can be considered temporarily robust. The same system may undergo the equivalent of a phase transition in thermodynamics to a different system or state when it is no longer robust. The discussion of robustness has parallels with the distinction Crawford Stanley (Buzz) Holling makes between engineering resilience and ecological resilience, where the former is the ability of a system to return to its initial state following external shocks and the latter is the ability of

a system to transform into a new state while still maintaining desirable functional attributes. In this context, the historic memory visible in many complex adaptive systems (CASs) can also be related to the idea of robustness as it implies that certain aspects of order are carried into new states.

Systems have inputs and outputs and are often divided into two categories, namely, closed systems and open systems. *Closed systems* are defined as systems that do not interact with their environment, thus remaining uninfluenced by externalities. *Open systems* have boundaries but exchange matter, energy, or information with their environment. The environment is often the collective term used for external and other systems, with a relationship to the defined system in consideration. In the real world, pure closed systems are assumed unrealistic and may only apply in abstract experiments.

Systems are also sometimes categorized as hard or soft systems. Hard systems (HSs) deal with well-defined problems in a systematic way. HS thinking treats quantifiable situations as problems that can be solved. Decision theory, forecasting, and simulation are all techniques used in this context—with individual actors or agents within the defined system not assigned complex motivations—and the outcomes aimed toward rational outcomes or at least known outputs. HSs thus deal with resolution. Soft systems methodology (SSM) starts with the assumption that the problem itself is not easily defined and hence difficult to quantify. SSM is used to address situations where people, motivations, and relationships are involved, and recognizes that the systemic understanding is dependent on the observer's objectives for the system. SSM thus addresses systemic cognition. Many real complex systems such as cities are made up of systems of systems and overlap the subjectivity of soft systems with the quantification of HSs, simply explained as the physical artifacts of a city being the outcome of human motivations.

Systems are defined or made apparent by the identification of their boundaries. Using systems theory, it becomes possible to connect components to components and systems to systems, and this can result in impenetrable definitions of extreme complexity that become impossible to analyze or utilize in any meaningful way. Hence, it is

important to define the boundary of a system with reference to context and function, with adequate awareness of environmental inputs and outputs. A system is typically identified by selecting the known entities that are inside the system and those that are outside, based on the ability to differentiate this identified group of entities from the others in terms of difference in type, structure, or collective behavior, and so forth.

Systems can also be understood as transformation processes with boundaries. This refers to a process or processes where inputs and outputs can be identified. While this last is often thought of as system used in mathematics or physics, where it may apply to thermodynamics, it can also be understood in terms of processes of immigration, in which the status of people's citizenship may change.

It is possible to study most if not all real-world phenomena as systems, through definition of these as linked systems, subsystems, and meta-systems. Complex systems are a special category of systems allowing the study of how relationships and processes between components result in unpredictable collective behaviors and how the system and its environment influence each other. Complex systems also enable the study of complex social and natural phenomena in mathematical and computational terms, bringing previously too-complex phenomena into the realm of scientific analysis.

Core Concepts: Nonlinearity, Emergence, and Self-Organization

Nonlinearity in systems is most strictly defined using two mathematical qualities. A system is formally nonlinear if it does not verify the properties of either superimposition or homogeneity. Both principles refer to the predictability of outputs based on known inputs. Hence, the principles remain unverified when output values do not behave as expected. The majority of real-world systems appear to be nonlinear, displaying qualities of positive and negative feedbacks, interference, and limitations in range when described using linear descriptions. Nonlinear systems are used in various disciplinary contexts, such as nonlinear regression in statistics, nonlinear optics in physics, and nonlinear population studies in ecology.

Emergence is the process by which smaller entities, components, and patterns interact with each other and in open systems with the environment, resulting in (typically larger) entities or behaviors not observable at the initial scale. This process is hence considered irreducible. In his definition, Jeffrey Goldstein, an economist, refers to the formation of novel and coherent structures and patterns during self-organization. Emergence can be seen as “strong” or “weak”; it is possible to simulate weak emergence using computers, but not strong emergence. Because identification of structure and pattern can be subjective depending on the definition of a system or choice of system scale, as can the interpretations of a pattern, emergence is often not considered to have a purely objective character. There appears to be general agreement, however, that emergence is related to synergetics—in other words, small-scale interactions resulting in a greater whole—and as in Hermann Haken's exploration of self-organizing structures in open systems, to multiple interacting subsystems. The theory of evolution provides a useful example and was used by George Henry Lewes, a philosopher of science, in his distinction between “resultants” and “emergents.” Resultants, according to Lewes, are phenomena that can be predicted by the preceding conditions. Emergents, on the other hand, as seen in evolution, refer to the possibility of completely new forms at various stages, despite being related to previous stages. There is a tendency to assume that emergence occurs in systems without top-down control, but certain degrees of organization, differentiation, and connectivity appear to be requirements for the process. Large numbers of interacting components—due to the higher number of interactions—are also often assumed to result in greater possibilities of emergence, but this may simply result in “noise,” which does not eventually result in emergent behavior and does not affect behavior at other scales. While there may be a minimum threshold of entities in specific systems for emergent processes to take place, it is the organization of the entities and types of relationships with particular reference to hierarchies and subsystems that appear to result in emergent outcomes. Emergent processes can occur due to both causal relationships and scalar interconnectivity. Phenomena observed in ant colonies and

flocks of flying geese are often used as the examples of emergence in action. One of the qualities of emergent systems is that they can interact with the environment as open systems and hence not follow the second law of thermodynamics; that is, thermal equilibrium through entropy.

Self-organization is closely related to emergence, but for the purposes of clarity, a distinction can be made by suggesting that emergence is a process more related to scale, while self-organization is more closely related to time. Self-organization is a process by which seemingly random structures and patterns can be seen to form in multientity systems without any observable or intentional top-down direction or controlling agent. The process can be observed in systems from many fields, such as physics, cognitive psychology, economics, sociology, medicine, and ecology. Behaviors such as swarming in biological systems or stock market crashes in economic systems can be studied as self-organizational processes. Negative and positive feedback loops amplify and dampen the fluctuations within a system, potentially contributing to the self-organized formation of structures and patterns. Although some definitions describe self-organization in the context of an isolated or uninfluenced system, biologists and ecologists acknowledge the relationship of organisms with their environment even during the study of self-organizational processes.

Complex Adaptive Systems

CASs are a particular group of complex systems, demonstrating some additional phenomena of particular importance to complexity in real-world systems. CASs—such as artificial intelligence (AI)—can exhibit the ability to learn from experience and evolutionary traits. Other qualities of CASs are sometimes identified as self-similarity, the ability of both agents in the system to adapt to changing conditions and the adaptability of the system itself. John H. Holland, a professor of psychology, computer science, and engineering, defined the term in a paper with the same name in 1992. He suggested that CASs not only have the ability to learn but may also demonstrate the ability to anticipate in the process of adapting to future conditions, thus adding yet another layer of

complexity. Many ecologies and human social group-based endeavors in a cultural and social system such as the global economy, political parties, or communities, including online tagging or social systems, can be studied as CASs. CASs can incorporate some or all qualities of complex systems (although sometimes named differently in disciplinary contexts, such as communication, cooperation, and spatial or temporal organization) and can be used in conjunction with game theory. Cities are increasingly used as examples of CASs. They are combined spatiotemporal and behavioral structures affected by, and affecting, the various individual and collective agents made up of citizens, socioeconomic subsystems, and sociotechnical endeavors, with multiple internal and environmental factors acting to influence the system at any one time, a system that is constantly in a state of becoming without a specific end state or aim.

Historic and Current Themes in Complex Systems

Complex systems, or the complexity sciences, have emerged over time through the identifiable overlapping influences of several disciplines and theories and remain an evolving body of knowledge today. Instead of attempting to identify specific historical stages leading up to the present state of complex systems, the following sections discuss, in roughly chronological order, the most widely recognized theoretical influences and movements related to and coming out the study of complex systems.

Chaos Theory

Chaos theory is the study of dynamic systems displaying seemingly random behaviors. Theoretically, chaotic systems are deterministic in that the same experiment should produce exactly the same results if the initial conditions are the same. The problem with this in practice is that absolute accuracy over an infinite length of time can only be theoretically achieved. In the 1880s, Henri Poincaré, a French mathematician also known as a theoretical physicist, engineer, and philosopher of science, experimented with a three-body system, a study of three or more interacting bodies that

attempts to determine the motions of three bodies over time, based on the knowledge of the initial masses, positions, and velocities of the three bodies. He found that the tiniest differences in initial conditions could result in dramatically different outcomes. Poincaré proved mathematically that increasing the accuracy of initial conditions when repeating the experiment did not result in proportional reduction in variation in the outcomes, which could continue to be dramatically different from the first experiment no matter how small the error, with the uncertainty in forecast increasing exponentially over time. In the 1950s and 1960s, Edward Norton Lorenz, an American mathematician and meteorologist, started to question the linear statistical models used in meteorology and the realistic accuracy of long-term predictions. While running computer models used to predict weather patterns, Lorenz chose to rerun a partially completed sequence and used the numbers noted from the end of the incomplete sequence, instead of starting from the beginning. He found that the results of his computer model were very different from expectations and deduced that this was because he had not used precisely the same numbers from the incomplete sequence but had instead rounded the numbers up or down by a decimal point. This led Lorenz to experiment with chaotic systems and conclude that the precision required to repeat predictable outcomes in such dynamic systems was possibly beyond the realm of human accuracy, resulting in the suggestion that prediction of past or present phenomena is in fact impossible. This theory was outlined in a 1963 paper for the New York Academy of Sciences and later presented at the 1972 meeting of the American Association for the Advancement of Science in Washington as what has since become widely known as the “butterfly effect.” Lorenz asked whether the flapping of a butterfly’s wings in Brazil could potentially result in a tornado in Texas. Although chaos theory is typically described in terms of extreme sensitivity to initial conditions, for a dynamic system to be termed chaotic, it also needs to be topologically mixed and have dense periodic orbits. Chaotic systems are unpredictable and yet deterministic in that the initial conditions determine future behavior. This means that despite their surface similarities, chaotic

systems and complex systems are usually differentiated.

Systems Theory

Systems theory, like complex systems, is not restricted to a single definition. It was developed in various disciplines, partly to allow for transdisciplinary frameworks and comparisons. Natural and human-related phenomena are the outcome of overlapping domains, and a systems theory approach attempts to provide a field of inquiry that allows this type of study and its reconciliation with traditional HSs. Systems theory may be considered a branch of systems thinking that enables the interdisciplinary consideration of areas previously treated separately by introducing the possibility of incorporating natural evolution and human subjectivity into the scientific study of all systems. As early as 1912 to 1917, Alexander Bogdanov, a Russian physician and philosopher, used the word *tektology* to refer to an approach unifying several disciplines from the social and biological to the hard sciences by understanding phenomena in terms of systems of relationships and organizational principles. Ludwig Von Bertalanffy (1901–1972) is widely accepted as having helped initiate the modern term, with his advance of general system theory, which he called *Allgemeine Systemlehre* and proposed as a solution to the fragmentation and duplication of research he had observed in various disciplinary fields. Both Bertalanffy, a philosopher by training, and Paul Weiss (1898–1989), a biologist, found that the existing mechanistic concepts inadequate for use with the natural systems that were part of their overlapping work. Bertalanffy clearly distinguished between *closed systems*—typically mechanistic systems—and *open systems*, which applied to living things by proposing that the laws of thermodynamics did not always apply to the latter. Early contributions to systems theory can also be traced to English mathematician and philosopher Alfred North Whitehead’s (1861–1947) view of the world as a network of interrelated processes, Talcott Parsons’s (1902–1979) action theory, and Niklas Luhmann’s (1927–1998) social systems theory. Systems theory influenced the development of ecological systems thinking, social systems theory, and systems science engineering.

Cybernetics

The French physicist and mathematician André-Marie Ampère first used the word *cybernetique* in 1834 in reference to civil government. However, it was Norbert Wiener (1894–1964) who popularized the word in its contemporary sense by writing a book called *Cybernetics: Or Control and Communication in the Animal and the Machine* in 1948. A Greek word meaning “steersman” provides the etymological basis for the term. Over time, multiple definitions for the field of cybernetics have come about due to its transdisciplinary appeal and usage. In a general sense, cybernetics is often referred to as a field concerned with the dual theories of communication and control, especially in the context of automatic control systems or self-correcting systems. However, a deeper study of cybernetics and its multiple definitions also allows inquiry into the directions the field has taken. Gordon Pask (1998–1996), an educational theorist, chose to interpret cybernetics as the art of manipulating defensible metaphors. Warren McCulloch (1898–1969), a philosopher, was interested in the internal and external communication of an observer within an environment. Gregory Bateson (1904–1980), an anthropologist, observed that cybernetics was focused on form and pattern. Stafford Beer (1926–2002), a management consultant, was interested in aspects of effective organization.

Although the multiple definitions for cybernetics expand the possibilities for application, most take into account the idea of how a system processes information and reacts to this information, with a chosen action or change to itself in order to improve either one or both of these tasks in the next iteration. Cybernetic systems typically refer to controlled systems, in which the organizational theorist Arthur J. Kuhn refers to detector, selector, and effector functions of a system. The detector is defined as concerned with the communication between systems, the selector is based on the rules of the system in terms of how decisions are made, and the effector concerns how transactions between systems take place. Examples of systems displaying cybernetic properties can be biological, cognitive, mechanical, social, and so forth. The nervous system is a biological example, while the autopilot system in an airplane is a mechanical example. Typically, cybernetics is associated with efficiency and identified

performative goals by being concerned more with what something does than what it is. This approach is the reason cybernetics is extremely transdisciplinary and potentially forms a meta-disciplinary language.

Some of the traditions that have existed in cybernetics can be compared side by side. Circular causality has been explored in the context of technology, in the form of regulation and control, and is particularly important in computation. Epistemology—the study of the nature and extent of knowledge—uses cybernetic ideas to study identity and autonomy in human social systems. Cybernetic systems are studied both in terms of how we observe them and in terms of how the systems observe themselves as well as other systems.

Systems theory and cybernetics are related historically and sometimes used interchangeably, but the origins of cybernetics are more associated with engineering fields, while general systems theory is thought to have emerged from a biological perspective. Cybernetics is associated with a wide range of phenomena and theories in the study of complex systems, such as cellular automata, game theory, and AI, the last of which emerged from cybernetics and later became distinct.

Artificial Intelligence

AI is a term coined by John McCarthy in 1955 as part of a summer workshop proposal at Dartmouth College. He defines it as the science and engineering involved in the making of intelligent machines. This definition has been generalized to the study and design of intelligent agents, where the term *intelligent agent* refers to a system that has the ability to perceive its environment and take action as a response. Whereas the original intention was to simulate human intelligence, this aspect known as “strong AI” has proved to be difficult in practice and remains a longer term goal. The two other aims, known as applied AI and cognitive simulation, have seen significant advances. Applied AI—also known as advanced information processing—is the field of development related to “smart” systems for commercial application. Cognitive simulation refers to the testing of theories about the functioning of the human mind, such as facial recognition.

The first widely acknowledged AI program was a checkers (draughts) program written by Christopher Strachey in 1951. This effort was advanced by Arthur Samuel, who by 1955 had developed a checkers program that could learn from experience, thus providing one of the first examples of evolutionary computing. John Holland's work in automating evolutionary computing has resulted in the advent of genetic algorithms.

Early work in AI is attributed to Alan Mathison Turing (1912–1954), who in his description of the “Turing machine” in 1935 provided the blueprint for the modern computer as we know it. Turing is also famous for formulating the Turing test in 1950, which is based on a computer convincing at least one third of designated interrogators into believing they are interacting with a human being. In 2014, a computer named “Eugene Goostman” passed the Turing test by convincing 10 of the 30 judges at the Royal Society in London. The validity of this test in proving a computer has displayed “human intelligence,” however, remains contested. In 1997, Deep Blue, a computer built by IBM, was able to defeat the world's reigning chess champion Gary Kasparov in a six-game match. The fact that human intervention was allowed to help Deep Blue in between games once again results in a debate about a computer's ability to learn, as opposed to simply processing huge amounts of information extremely quickly.

The primary areas of AI research include learning, problem-solving, reasoning, language, and perception. Research can be understood as two potentially distinct methods, the first being the “symbolic” approach and the second the “connectionist” approach. These can be thought of as top-down and bottom-up, respectively. While the symbolic approach has seen advances over the years, connectionist approaches have experienced renewed interest since the 1980s. The approach of training artificial neural networks embodied in the bottom-up approach has been applied in the context of visual perception, financial analysis, telecommunications, medicine, and language processing and is related to certain types of machine learning. Nouvelle AI, which describes systems referring to the external world instead of to an internal model only, and its related “situated”—embodied intelligences in the real world—approach, has refocused

attention on Turing's discussions on machine sensing from external environments.

Dynamical Systems

The theory of dynamical systems is relevant to the study of long-term system behavior using mathematical equations, particularly in mechanical or deterministic systems. Mathematical models are utilized to predict systemic change in time or dimension. Although the classic example is the predictability of the position of a clock in time, dynamical systems have also been used in the context of natural phenomena such as the changing number of fish in a lake over the seasons. Dynamical systems study today mainly focuses on chaotic systems and has been used over time to try and understand the movement of the solar system, weather, growth of crystals, traffic jams, and the motion of a billiard ball.

Agent-Based Modeling

Agent-based models (ABMs) are a specific type of computational model used to simulate and study agent behavior and the resulting effect on a system. Agents in this context can be individual or collective entities and typically interact within an environment they can perceive. The basic idea is that simple behavioral rules result in complex behaviors. ABMs are widely used in the social sciences and contain elements of AI, computational sociology, multiagent programming, emergence, and game theory. Possibilities of probability and randomness can be introduced into agent interactions.

Fuzzy Logic

Fuzzy logic is applied when the categorization of things into distinct sets cannot be accomplished easily. The term was introduced by Lotfi A. Zadeh in 1965. A typical example is an attempt to define the exact point when a statement changes from false to true, from black to white within a smooth gradient. Fuzzy logic states that there is an infinite gray area between black and white, which is defined partially on the basis of subjectivity and context. People are typically able to assign a value

to the truthfulness of a statement using numbers between 0 and 1 or the modifiers “quite true” or “mostly false.” Zadeh suggested that precise statements lost their meaning as complexity rose, thus positing that fuzzy categorization was more appropriate for complex systems.

Data Mining

Data mining is the process of analyzing data from multiple perspectives and either summarizing it into understandable information structures or discovering useful patterns and correlations. While the term is often used to refer to large-scale information processing, the useful applications overlap with machine learning and its supervised and unsupervised learning methods. Machine learning is a branch of AI, which has come to the forefront with the advent of Big Data. Examples of machine learning can be found in search engines’ ranking websites and junk mail filters learning usage. Medical databases are currently being created and analyzed to create knowledge for diagnosis and cures, and recent developments in computer vision and natural-language processing have begun to demonstrate direct translation of real-world knowledge into digitally recognizable data without the need for tagging or prior categorization.

Case-Based Reasoning

Case-based reasoning (CBR), or case-based modeling, attempts to find solutions to new problems based on the solutions of similar problems in the past. CBR can be observed in many fields, such as the use of legal precedents in law, and is becoming a popular methodology for both computer reasoning and human problem-solving. It is useful to observe the innate learning ability of the method as new cases are solved and additional cases are incrementally added to the systems solutions data. This last quality relates CBR to CASSs.

CONCEPT

A concept is akin to a general or abstract idea. The philosopher Hilary Putnam famously said that concepts are signs used in a certain way. This is similar to the 18th-century philosopher David Hume's notion that an abstract idea is an exemplar along with a rule of use. Whereas those thoughts are powerful, they can be hard to grasp at first, and we can think of concepts in a variety of ways. A concept can be an intuited object of thought or it might be directly conceived. When someone says that they know a concept, then it means that they comes across one *in action*, because it becomes larger and greater than its label as a word, phrase, clause, or sentence. Generally, every idea, object, issue, process, person, and place can develop into a concept. A standard example is the concept of triangle. The concept of triangle is not, itself, a triangle but instead allows us to reason about all triangles by reasoning about it. We can learn about all triangles by investigating the properties they all share, and we do that by investigating the concept. It is an integral part of human cognition, and various approaches and viewpoints are presented by the scholars to define it. Concepts cannot appear in isolation as they are employed to represent knowledge. During any such practical representation, concepts remain associated with other.

Definitions of Concepts

The term *concept* was derived from the Latin word *conceptum* (*that which is conceived*). The explanation of a concept has been dealt with in the subject matter of psychology, linguistics, and philosophy. Many theories, sometimes fundamentally contradicting each other, have been proposed about the nature of concepts over time. When researchers try to define explicitly what a concept is, they may fail insofar as a universally accepted definition of a concept does not exist. However, it is generally recognized that concepts are somehow associated with the process of human cognition. Moreover, it is commonly accepted that concepts are universal and abstract. Since concepts do not enclose the differences between or specifics of the objects to which they apply, they are considered

abstract. Therefore, all objects to which a concept applies, known as *extensions* of concepts, are treated as indistinguishable from the respective concept. The universality of concepts arises from the fact that they apply to every object in their extension. The abstract nature of concepts does not affect the nature of objects in the extension of a concept. These objects can thus be real or imaginary, atomic or composed, abstract or concrete. A concept can be anything existing in the human mind, such as a strategy or way of thinking, or shared through behavior and human language, including actions and tasks.

Concepts in Philosophy

The ancient Greek philosopher Aristotle was the first to provide the classical theory of concepts. Aristotle's *theory of definition* defined a concept by comparing a pair of concepts which he termed as *genus* (a sort, kind, or family) and *differentia* (a distinguishing characteristic). His theory defines the concept *human*, for example, as a *thinking animal*. The *animal* determines the family human belongs to, which corresponds to genus, and it is *thinking* that distinguishes humans from other animals, and thus corresponds to differentia.

Philosophers Arthur Schopenhauer and John Locke consider individual experience, in the form of sensation and reflection, to be responsible for the formation of concepts. They considered concepts to be abstractions. The concepts abstracted from human experience are also known as *posteriori* concepts. Another type of concept introduced by the philosopher Immanuel Kant. He mentions pure or *a priori* categories or concepts that originate in the human mind. The concepts of time and space are Kant's examples of *a priori* concepts.

The philosopher, logician, and mathematician Gottlob Frege argued that we comprehend the world around us through concepts. He provides illustrations of a symbol (*sign*), an object (*reference*), and a concept (*sense*) to show the differences between them. The symbols *morning star* and *evening star* refer to the same object: the planet Venus. However, the concepts of these two phrases are entirely different. The former can be observed in the morning, while the latter is visible in the evening. The two signs represent two different senses which correspond to different observations of the

world, namely the time and space of observation in the *star* example.

Similarly, John Sowa considers a concept as a mediator that relates a sign to its reference. This mediation can be presented with the triangle, popularly known as a *semiotic triangle*, put forward in the 1920s by I. A. Richards and Charles K. Ogden. If we want to show a person and her activity in the triangle, the lower two corners show an icon resembling a person and the other corner will show the printed symbol representing her name, for example, Mary. The peak of the triangle will represent a *neural excitation*, for example, how someone thinks of her at a particular time and space. This *neural excitation* is a mediator between the symbol and its object, and it is referred to as a *concept*. In the field of philosophy, concepts are directly associated with the perception of the world and essence of human existence. But in other fields of science, this treatment is more pragmatic. Concepts are expressed in terms of the field's terminology, depending upon the way concepts are employed in practice.

Concepts and Other Scientific Disciplines

In language science, a concept is generally considered as a unit of meaning, often formed through the abstraction of concrete phrases and words that correspond to the conceptual meaning. For example, WordNet, a lexical database, illustrates the linguistic treatment of concepts. This database interconnects nouns, verbs, attributes, and adverbs in the English language. For concepts, WordNet defines them through sets of synonym words called *synsets*. A synset consists of synonym words, such as man, human being, homo, and human, which define a concept that can be lexically expressed by any of the words in the synset. Additionally, WordNet provides an explicit definition in the description of the synset *concept*. The WordNet example shows that a concept can be represented with more than one lexicon. Moreover, when individual words are represented with more than one meaning, then they can stand for more than one concept. On the other hand, the significance between words and concepts can be understood by the fact that concepts are language-independent, unlike words. When doing translation between different languages, the semantic

aspect of words is expressed and preserved to a large extent. Beside several other definitions of concepts in linguistics, some define it as a common meaningful shared entity in the mind of users.

In engineering, a concept is concerned with building models of entities from reality. Such perspective defines concepts as creatures of the computational field, which presents through their representations in software such as XML and UML and in systems of axioms. In defining concept, mathematics, unlike engineering, transcends the reality that is recognized through our intuition and emotions. Mathematician Carl Benjamin Boyer defines mathematical concepts, such as *derivative* and *integral*, as abstract mental constructs. He states that such concepts are beyond the world of sensory experience; however, they may be observed by abstraction from nature or by intuition.

Concepts and Knowledge Representations

As discussed in the previous section, concepts are often considered as atomic elements in knowledge representations. For that reason, it is worth knowing how concepts are treated in this domain. Certain formalisms represent organized knowledge as concept maps and define concepts as perceived regularities in objects or events, or records of objects or events, termed as *labels*. For most concepts, the label is a symbol or a word. One formalism is description logic, used for representing logic-based knowledge through classes (concepts), relations (roles), and objects (individuals). The concepts denote sets of individual objects in description logic.

Frames are knowledge representation structures influenced by the organization of human memory. Contrary to other many formalisms for representing knowledge, concepts are not regarded as atomic units when represented by frames. They are considered as sets of highly structured entities which can be marked with recursive structures comprising pairs of slots (also known as *attributes* or *properties*) and their values. Object-oriented languages are closely related to frames. They discern two elemental structures: classes and their instances, known as *objects*. A class specifies the methods and properties that can be applied to

control the properties of all the objects that are instances of a special class. The set of methods and properties in a class allow for those objects possessing a behavior and a state. As classes act as abstractions of concrete objects, they stand for concepts, whereas objects represent instantiations of concepts.

Concepts and Implicit Definitions

It is important for a machine—as in the instance of the lexical database discussed earlier in this entry—to recognize and define concepts consistently and exactly. If such a machine fails, for example, to recognize which text represents concepts and which does not, then it becomes difficult to make concepts recognizable so that they can be extracted automatically from any type of texts.

A solution is proposed by a vector space model (VSM). In a VSM, each document corresponds to a vector with coordinates representing the frequency of the detected index items in a document. The number of dimensions of each vector corresponds to the number of index terms detected in a document collection. The measurement of two documents, such as the level of similarity between two documents, can be done by calculating the inverse function of the angle between them or the inner product of the corresponding index vectors when the similarity function is at a maximum and the angle between two vectors is zero. The measurement of documents can also be observed in terms of similarity when a new index item is given to a document collection. If there is a decrease in similarity level, then the newly assigned index item has a high discrimination value, and it is considered as a *good* index term. The opposite of this is true for a *bad* index term. For this reason, the *good* index terms can be known as *concepts*, as they represent even the smallest units of knowledge bearing as much meaning as possible; in other words, this representation is enough to decrease the similarity level between the documents when given to a document collection.

The field of word-sense disambiguation, especially automatic identification of word senses (also known as word-sense disambiguation), also provides more implicit definitions of concepts. The word clustering approach to the word-sense induction involves clustering of semantically

similar words, such as they can produce a specific meaning and can thus be considered as concepts. The similarity between different words can be determined by the observation of the syntactic dependencies of specific words in actual texts, for example, words functioning as grammatical subjects of a transitive verb, direct objects of a ditransitive verb, adjectives, and so on. In this way, concepts can be defined implicitly as a group of words that share a high degree of syntactic dependencies. Many other approaches and algorithms exist. The commonality between them is the clustering or grouping of words showing distinct meanings. These clusters are known as *concepts*. The exactness of words in defining a concept, however, varies, and it depends upon the definition of similarity that a particular method uses for grouping words.

As we have seen, there are various possible ways through which we can define concepts. In the following section, we will discuss how concepts can be organized and thus be made predictably available for use.

Concepts and Their Relationships

It is necessary for concepts to be linked with each other, and they cannot be isolated for any practical use in representing knowledge. They are the chief means of organizing concepts. The relationships that link one concept to another are employed in day-to-day communication and the significance of identifying the underlying relationships between concepts can be understood with the following example. The statement “Mary has an Intelligence Quotient of 140” clearly states a very explicit relationship that Mary has some characteristic named Intelligence Quotient that is equal to 140. Nonetheless, the statement implies many other implicit relationships. These relationships include things like the abbreviation of Intelligence Quotient as IQ or the value 141 follows 140 and it is preceded by 139, or Mary is commonly a female first name of a human, or that an IQ equal to 140 shows a person of high intelligence, and so forth. But if context is lost, then many things described in this statement are also lost. We will not get any meaning in isolation, for meaning is the sum total of relationships. Here, semantic relations are important. They are the basic means of organizing

concepts into knowledge structures. The meaningful associations between two or more entities or concepts are also known as *semantic relations*.

Valence is a basic property of semantic relations. It includes the number of concepts a semantic relation can associate. The valence of a semantic relation is expressed with the number of fields, slots, places, or sides of the relation. Mostly, the relations connect two concepts, and they remain binary. However, the relation of *send* is, for example, a ternary relation, connecting the one who sends, the one who receives, and that which is sent. Relations where there is higher valence than two can be decomposed into more than one binary relation. As mentioned earlier, all relations can be represented as concepts that are linked with a single *link* relation.

The pioneering linguist and semiotician Ferdinand de Saussure distinguishes two types of basic semantic relations: syntagmatic and paradigmatic relations. A *syntagmatic* relation is a relation between two neighboring concepts in the texts, such as a syntagmatic relation is the relation “loves” linking the concepts “John” and “Mary” in the sentence “John loves Mary.” This relationship holds for an ad hoc association of concepts in an actual text. By contrast, a *paradigmatic* relation is a relation between concepts that is independent of the actual use of the respective concepts in the texts, such as the concepts *loves* is inherently associated with the concept *act of loving* by the paradigmatic relation *is an act of*. Some formalisms for concept organization recognize a special type of relation known as an *attribute* for Semantic Web ontology languages and object-oriented modeling languages. The properties of concepts and their extensions are denoted by attributes. They are generally represented as a feature of entity that is employed to extension and model concepts. The attributes can be classified into four groups: Certain values remain attached and associated with the concept. *Class attributes* assign such values to the concept, and thus remain the same for all instances of a concept; *instance attributes* assign different values to each extension of a concept; *local attributes* share same-name with attributes that are attached to different concepts; and *global attributes* are applied to all concepts, for example in ontology, in a specific conceptual structure.

Concepts and Graphical Organizations

Semantic relations often result in a graph-like structure while organizing concepts. Such graphic structures are commonly described with a formalism, for instance, concept maps, semantic networks, and conceptual graphs. A concept map is comprised of concepts and the relationships between them. The relationship is expressed with phrases and words mentioned on the corners, linking concepts. This relationship forms meaningful statements, or propositions about constructed or naturally occurring events or objects in the world. A conceptual graph has two modes: conceptual relations and concepts. Any graph can present concepts in a number of ways such as rectangles and circles. The conceptual relation links with a concept at the edge of the conceptual graph. The organization of concepts remains hierarchical in concept maps. The general concepts remain on the top, whereas specific concepts are located in the bottom.

CONCEPTUAL ANALYSIS

Conceptual analysis, also known as *explication* among empirical researchers, is a fundamental logical step of scientific inquiry and theory development. It builds a detailed and comprehensive definition of a concept, normally also including empirical measurements or indicators of that concept. In science, particularly social science, no theory can be built without such a comprehensive clarification and articulation of the concepts that are needed to establish a hypothesis, which turns to be a theory if it passes substantial empirical tests. Nowadays, many academic debates are the result of unclear concepts.

Conceptual analysis is philosophically rooted in linguistic philosophy, which holds that language is systematically misleading and therefore needs to be carefully analyzed. With roots that can be traced to the beginnings of philosophy and logic, conceptual analysis was highly exalted by analytical philosophers such as Rudolf Carnap (1891–1970), who held that scientific concepts must be analyzed and defined by philosophers. In the 1950–1960s, however, philosophers like W. V. O. Quine (1908–2000) and Hilary Putnam (1926–2016) were convinced that analysis to produce a priori concepts was not possible nor necessary. Conceptual analysis has been undergoing a revival in philosophy in recent decades, widely attributed to Australian philosopher Frank Jackson's work. According to philosophers including Stephen Stich and Jonathan Weinberg, Jackson's 1998 book *From Metaphysics to Ethics: A Defense of Conceptual Analysis* provides perhaps the most sophisticated defense of the use of conceptual analysis in philosophy that has ever been offered. In it, Jackson argues that the very business of telling a story

in the vocabulary of daily life requires grasping the essential structures of the concepts and therefore the exercise of conceptual analysis, which is an important tool for understanding the material world and the foundation of categorization, meaning construction, and communication. All theory construction is dependent on conceptual analysis. In science and social science, researchers have also developed guidelines for conceptual analysis in all empirical studies.

Concepts, Constructs, and Variables

Concepts, in their widely adopted sense, are the basic unit of thoughts and statements. They are mental representations, categorizations, and labels for things being observed in the real world. Ontologically, concepts have been deemed by philosophers (e.g., John Locke, David Hume, Jerry Fodor, and others) as mental representations/images (lately popular among psychologists and other social scientists), abilities particular to cognitive agents (see, e.g., Michael, Dummett), or Fregean senses/abstract objects (see, e.g., Christopher Peacocke). The classical theory of concepts, which is held in the highest regard among all theories of concepts, maintains that all concepts are expressed in languages and their definitions consist of simpler concepts. Definitions of complex concepts beyond common sense are mostly acquired through paradigmatic conceptual analyses. In science, conceptual analyses are ongoing as a theory is developed.

An important task for social scientists in building social science theories is to test and identify causal relationships between or among concepts. In social science, those concepts are related to human reflection and the society. *Constructs*, a term popularized at least partly by education researcher Fred Kerlinger in his oft-cited book *Foundations of Behavioral Research*, are a special type of concepts invented by researchers for the purpose of scientific inquiry; concepts usually have multiple dimensions. For Kerlinger, *weight* is a concept, but *intelligence* is a construct. Other scholars, for instance, communication researcher Steven Chaffee, well known in part for his monograph *Explication*, simply use the word *concepts* in both situations that Kerlinger mentioned. The

monograph is in fact a part of the series *Communication Concepts*, which examines communication concepts that have long attracted scholarly interest. All concepts should be carefully analyzed before being used to build propositions (hypotheses). In *Explication*, Chaffee showed how the concept *age* needs meticulous examination. In some cases, ages reported in years and those calculated with birth dates are not even correlated.

Concepts, including Kerlinger's constructs, are not directly observable. To study the concepts, social scientists, particularly those who use statistical techniques in research, need to analyze and define them, and develop one or more indicators from them. Those observable and measurable indicators mostly contain variation and are therefore called *variables*. The lengthy and replicable process of searching for the definition of, and developing indicators from, concepts is called *explication*.

The Process of Explication

Several philosophers have talked about explication, such as Immanuel Kant and Edmund Husserl, but Rudolf Carnap is most well known as the one who valued explication in scientific theory construction. He defined explication as the logical analysis and construction to clarify a concept that is vague or not exact in daily life or an earlier stage of science. For old concepts, explication is conducted through searching out new definitions that are clearer, simpler, more exact, and, above all, fit into a systematic structure of scientific concepts. The more a concept is brought into the system of other scientific concepts through explication, the more fruitful and useful the concept is to construct theories or laws. Explication, Carnap said, is one of the most important tasks of philosophy.

Social scientists have divided explication into two steps: conceptualization and operationalization. Conceptualization, what communication researcher Steven Chaffee called *meaning analysis* in his *Explication*, is the process of articulating the essential meaning of the concepts. The meaning of a concept, according to Chaffee, can be defined in two ways: by distillation and by list (similar to the traditional logic terms *intension* or *connotation* and *extension* or *denotation*). *Distillation* consists

of the abstract statements of the essential elements of the concept (intension or connotation). For instance, media dependency is a media effect that when audience have no access to other communications on a topic they depend maximally on the mass media. In definition by list (extension or denotation), all concepts subordinate to the concept that needs definition are listed. The concept of mass media, Chaffee suggested, would be better to be defined by list as including newspapers, books, magazines, television, radio, and films. A distillation definition of the concept *mass media* is not easy to produce, as scholars are unclear whether the *mass* refers to mass production, mass audiences, or both.

Authors who use a concept without conceptualization may adopt different meanings of the same concept in the same literature and thus confuse themselves and readers. Chaffee and his coauthor found that some communication researchers used the term *social reality* to refer to the real social situation that existed even though people in the situation might not see it, while other communication researchers used the same term to refer to the false reality socially defined by people in it. The understanding of the relationship between communication and the *social reality* in this literature, therefore, cannot be solid.

Operationalization is the step, based on conceptualization, of finding empirical definitions (also called *operational definition* by some social scientists) for the concepts. Those empirical definitions can be directly observed and measured, and represent the essence of, but never the whole, concepts. Finding those empirical definitions is the ultimate goal of explication. No concept, according to empiricism, can be scientifically studied without an empirical definition that can be directly measured. In psychology and education research, studies on how to develop empirical definitions or measurements of concepts constitute an important and fundamental subfield. Obtaining adequate measurement methods, psychologist Jum Nunnally argued, is the major problem in the science of psychology. Nunnally believed that psychological theories were filled with concepts that could not be accurately measured, which hindered the development of psychological science. Communication researcher Sharon Dunwoody also mentioned that a concept

measured inaccurately in her research nearly invalidated a line of her work for 15 years and made her aware of the significance of explication in social science research. For a long time, she studied how the concept *uncertainty*, which she conceptualized as public perception of what the scientists didn't know about an issue, impacted the information use of members of the public for the purpose of making risk judgments about that issue. They measured that concept by asking respondents about their level of uncertainty, and later found that for most of the respondents the word *uncertainty* actually meant how much they themselves didn't know of the issue.

Many instances of confusion in social sciences have arisen from malfunctioning conceptualization and/or operationalization of concepts. The dispute between second-level agenda-setting researchers and framing-setting researchers in the mass communication field, for instance, is largely caused by unclear definitions of the concepts *agenda* and *frame*. *Agenda*, a good metaphor, is accurately operationalized as the number of stories in the original agenda-setting study conducted by Maxwell McCombs and Donald Shaw. But when studies citing agenda-setting theory accumulate, particularly when the agenda-setting theory is extended to its second level (from objects to attributes), the concept *agenda* becomes ambiguous and is defined in a variety of different ways. The same is true of *frames*. Although frames have been conceptualized as the way of defining meanings in the texts and operationalized as rhetorical devices, patterns of message organizations, word choices, tone, and so on, other scholars have observed that some framing researchers just operationalize frames as issue topics. As a result of these ineffective conceptualizations and operationalizations, the salience of a story is used in some studies as a measurement of second-level agendas but in other studies as a measurement of frames, thus leading to the dispute that each school claims that the other school is a part of its own research. In the field of international relations studies, David Baldwin found that much theoretical controversy had been generated due to the unclear explication of the concept *dependence* and related concepts such as *interdependence* and *dependency*. Marketing researcher Charles Young also finds that different

marketing research companies, such as Ameritest, MSW, Milward Brown, Ipsos-ASI, and ARS, use different concepts not only to document campaign effects but also measure the same concepts, such as attention, recall, motivation, persuasion, and brand linkage, in totally different ways. Those different measurements of the same concepts, Young notes, generate confusion in the industry.

Dimensions and Levels of Measurement

For empirical researchers, a successful explication of a concept should end with a measurable empirical definition, a variable that can be used in data collection and statistical analysis. A variable can have one or more than one observational point (indicator). What is more, some concepts, called constructs by some researchers, contain different perspectives (dimensions), and each perspective may demand several indicators. For instance, through literature review, Alice Eagly and Shelly Chaiken identified three dimensions in human attitudes: cognitive, affective, and behavioral, each of those perspectives having several indicators. Although single-item measurement is often seen in scientific research, to reduce measurement errors in order to close the gap between empirical definitions and the concept that they measure, multiple-item measurement for a single-dimension variable or for a dimension of a multiple-dimension variable is strongly suggested in social science.

Scientific investigators usually measure variables at four levels: nominal (categorical), ordinal, interval, and ratio. Nominal level is the lowest; each number only represents a category and the numbers cannot be compared for a ranking. A common example of a nominal-level measurement is gender. Male = 1 or female = 1 is just a labeling of different genders and has no numerical meanings. The second level, ordinal, enables comparison and ranking, but values at this level still cannot be mathematically calculated in any way, because values between data points are unknown. For instance, movie A, B, C, and D are ranked as 1, 2, 3, and 4 with 1 being the most favorable ranking. The measurement clearly shows the level of favorability of those four movies. But one cannot say that the difference of

favorability between A and B is exactly the same as that difference between C and D. Interval level, beyond ordinal level, makes addition and subtraction possible but not multiplication and division. Interval scales place greater emphasis on a number's relationship with other numbers than on the numerical values of the numbers. Examples of interval level of measurement include temperature and IQ score. John's IQ score of 108 is 8 units higher than David's IQ score of 100, and that difference is smaller than the difference between Josh's IQ score of 102 and Mike's IQ score of 98. If the whole IQ scale from 0 to 200 is systematically changed to 300 to 500 or 700 to 900, no information contained in the IQ measurements will be changed, because numbers in interval scales have only comparative values and no absolute numerical values. At the ratio level, such systematic change of a whole scale is no longer feasible. Age and income are the examples normally measured at the ratio level. Changing Hank's \$4 to \$9 and Bob's \$3 to \$8, even though the comparison value between Hank and Bob's money has not been changed, the absolute values of their moneys have. In attitudinal research, scholars tend to use Likert-type scaling, Guttman scaling, Thurstone scaling, and semantic differential scaling to measure concepts. Those scales normally contain five to nine measuring points. Some conservative scholars analyze data collected with those scales at the ordinal level, but most scholars use them as interval-level measurements.

Reliability and Validity

Because the explication process goes a long way from the unobservable conceptual world to the measurable real world, information may get lost during the journey of conceptual analysis and errors may occur. All empirical measurements inevitably have some deviation from the concepts that they represent. In psychology and other social sciences, the accuracy of those operational definitions as results of conceptual analyses is documented by two indicators: reliability and validity.

Reliability documents how consistently the measurement is perceived, consciously or unconsciously, as an operational definition of the concept being studied among people. It is therefore

also called *dependability*, *stability*, *consistency*, or *predictability* by some researchers. Reliability essentially examines how many errors are produced simply because of misunderstanding of the operational definition or the ways of using those operational definitions. A reliable operational definition will be interpreted the same way from time to time and situation to situation by different respondents, whereas an unreliable one will be interpreted differently at different times or in different situations or by different people. Reliability can be tested in several ways, such as testing the same operational definition for multiple times or analyzing the internal relationship of components of an operational definition. In most areas in social science, when multiple items are used to explain a concept, a commonly used coefficient of reliability is *Cronbach's alpha*, which measures the internal consistency among the items that serve as indicators of that concept.

Validity documents the deviation of the operational definition from the real, consensual meaning of the concept being defined. It checks whether or not the operational definitions really measure what the researchers think that they are measuring, the concept. Based on how the deviation is checked, measurements have different types of validities. A joint committee of the American Psychology Association, The American Educational Research Association, and the National Council on Measurement Used in Education classify validity into four categories: content, predictive, concurrent, and construct. If a group of experts examine the operational definition and judge it as an accurate and comprehensive representation of the concept, then the operational definition has content validity. Predictive validity and concurrent validity both check the operational definition against an outside criterion to see if the empirical definition represents the concept accurately and comprehensively. There are therefore both called *criterion validities* also. The only difference is the times of the formation of the criterion and the checking of the operational definition against the criterion. For predictive validity, the outside criterion will be formed in the future, and so will the comparison of the operational definition against the criteria. But for concurrent validity, the outside criterion exists in the current time

and can be used to check the validity of the operational definition immediately. For instance, to check if a test to identify characteristics of a great journalist really measures what it claims to measure, a sampled group of journalists can be asked to take the test. If journalists who have done well in their job score high on the test and those who have done poorly score low, the test has concurrent validity. If the test is administered to a sampled group of college journalism students, and years after graduation those who score high on the test perform well as journalists while those who score low perform poorly, then the test has predictive validity.

Construct validity is based on the examination of a concept with related concepts, sort of like Carnap's system of scientific concepts. Construct validation is possible when two conditions are met: (1) From literature or experiences researchers know the relationships of the concept being analyzed with other existing concepts; and (2) those related concepts have known valid operational definitions or measurements already. To check the construct validity of the operational definition of a concept, researchers examine the relationships of that operational definition with the known valid operational definitions of concepts related to that concept. If the relationships between that operational definition and the other operational definitions are the same as the known relationships between that concept and the related concepts, the construct validity of that operational definition for that concept is then established. Otherwise, the conceptual analysis for that concept needs to continue until a valid operational definition is established so that the concept can be further studied in a hypothesis or a theoretical system, namely, a model. Construct validation is, as Kerlinger said, like using the whole process of developing a theory to develop an empirical measurement for a concept. In research practice, Kerlinger recommended to use factor analysis to check the validity of the measurement of a concept or examine the correlations among the measurements of two or more concepts. Recently, most researchers prefer using confirmative factor analysis or *structural equation modeling*, also called *latent variable modeling*, *path model*, or *covariance structural modeling*, to conduct construct validity analyses.

For instance, in an article published in *Molecular Psychiatry* in 2010, K. S. Kendler and M. C. Neale used a structural equation model, which they called a *path model*, to analyze the relationship between the construct *endophenotype* and other related concepts. Other methods of construct validity analysis also exist. For example, a group of researchers from Bowling Green State University, Annette Mahoney, Kenneth Pargament, Nalini Tarakeshwar, and Aaron Swank, used a meta-analysis of 94 studies published in the 1980s and 1990s to clarify the linkage of the concept of religion with other concepts in the family domain.

Finally, an unreliable operational definition cannot be a valid one, but reliability also does not guarantee validity. A valid definition, however, theoretically should be a reliable one. Unreliable or invalid operational definitions of scientific concepts can damage any scientific investigation. Having valid definitions of its fundamental concepts marks the maturity of a scientific field. To achieve that maturity is still a heavy duty for emerging areas of social scientific research. Even in some areas considered well developed, such as media effects research, as James Potter said when he attempted to explicate the concept *media effects*, the continual clarification of the central concepts in those areas is still the essential scholarly task.

CONCEPTUAL BLENDING

Conceptual blending is the popular name for a theory of idea creation and emergence that draws heavily from the work of Arthur Koestler in the 1960s and is most popularly associated with the work of Gilles Fauconnier and Mark Turner. Attempting to describe the functional and theoretical aspects of how humans think creatively and develop ideas, conceptual blending has recently been adopted in various fields as a framework for developing software and artificial intelligence, educational approaches, scientific inquiry, and, perhaps most commonly, linguistics. Methods for visualizing complex information have also started to incorporate conceptual blending as a way of addressing metacognition and intention in learning processes.

Matrices and Bisociation

Working to address issues of human creativity, Arthur Koestler (1905–1983) published *The Act of Creation* in 1964. In his book, Koestler conceives of frames containing individual concepts, whether creative or factual. These frames, which Koestler refers to as *matrices*, can be thought of as Euclidean two-dimensional planes (imagine a sheet of paper) which bound and contain the concept entertained in the mind of a thinker. The ability to entertain these individual concepts is not necessarily a creative act. In Koestler's model, the creative process occurs when two or more of these planes intersect. The point(s) of intersection between the matrices are the locus of the creative act wherein two or more concepts interact with one another in the mind of the thinker. Koestler refers to this active process of conceptual interaction as *bisociation*:

I have coined the term 'bisociation' in order to make a distinction between the routine skills of thinking on a single 'plane' as it were, and the creative act, which [. . .] operates on more than one plane. The former can be called single-minded, the latter double-minded, transitory state of unstable equilibrium where the balance of both emotion and thought is disturbed. (p. 36)

The bisociation approach to considering conceptual interaction encourages the investigation of

topics like narrative, humor, art, and science through a lens of emergence rather than delineated cycles of start–finish. The interaction of matrices can itself produce new matrices and in doing so contributes to an evolutionary model of concept creation and adaptation. Koestler applies this view to scientific inquiry explaining the additive process of connecting one instance of research with another to create new findings, theories, and concepts:

In the discoveries of science, the bisociated matrices merge in a new synthesis, which in turn merges with others on a higher level of the hierarchy; it is a process of successive confluences towards unitary, universal laws. (p. 39)

Mental Spaces and Cross-Space Mapping

The contemporary model of conceptual blending is most notably attributed to the work of Gilles Fauconnier and Mark Turner. Their 2002 book *The Way We Think: Conceptual Blending and the Mind's Hidden Complexities* draws heavily from the concepts Koestler identifies. Their work is predicated primarily on linguistic constructions and uses a network model (connections between related concepts) to conceptualize how people entertain multiple concepts and synthesize new ones. In this model, Fauconnier and Turner conceive of mental spaces as “small conceptual packets constructed as we think and talk for purposes of local understanding” (2003, p. 58). These mental spaces are contextual in nature and often have short life spans.

When mental spaces merge, they can aid in constructing new conceptions passing through phases Fauconnier and Turner refer to as *cross-space* mapping. This process progresses to a final step they term as *blend*. This final step is important to understanding concepts but more important to the creation of new ones. In most cases, the term *conceptual blending* refers to the process of mental spaces colliding in these cross-space maps analogous to the intersecting matrices in Koestler's model.

For example, if one person is attempting to describe a platypus to another person, they might describe it as a combination of a duck's bill and a beaver's body. For the duration of the conversation (or even shorter), the individuals may construct mental spaces where they can consider each

of these animals. Cross-space mapping takes place when the individuals entertain the implications of these mental spaces interacting with one another. Thus, in considering a platypus as a duck/beaver hybrid, conceptual blending leads to a mental image in the minds of the individuals. This blending does not guarantee accuracy, the process is inherently subjective, but a strong understanding of the process can help to improve creative and abstract reasoning as well as an individual's ability to engage in more systematic processes, such as scientific research, by drawing connections between dissimilar ideas or concepts.

Fields of Application

Although in its infancy, computational methods of investigating conceptual blending are used in research about user-interface design in computer software and structuring artificial intelligence systems. Some research into humor and metaphor engages conceptual blending theory. In a paper published as a result of a conference, State of Research Into Critical Thinking, it was clear that educational communication required skills and approaches beyond classic delineations of communication or linguistics. Conceptual blending has begun to be used as the basis of pedagogical strategies in educational literature.

As the traditional line between print and digital culture blurs, conceptual blending becomes increasingly useful in the study of linguistic approaches to communication and information exchange. Various approaches to linguistics and cognitive processing have employed conceptual blending as a framework through which to address human thought processes. Seana Coulson discusses conceptual blending in her 2001 book *Semantic Leaps: Frame-Shifting and Conceptual Blending in Meaning Construction*, in which she connects the approach to theoretical models of scripting and framing, among others.

Conceptual blending also connects two important aspects of learning about concepts (and by extension theory): metacognition and intention. Metacognition refers to thinking about one's own thoughts and intentionality has to do with students who engage in willful steps to construct meaning (see Hennessey, 2003; also Brown 1978; Flavell, 1976; Sinatra & Pintrich, 2003). In order

to support these aspects of the learning process, it is important to occasionally step outside of the traditional linguistic constructs often used to consider human communication and inform the various traditions of scientific inquiry.

James Sosnoski (2015) uses conceptual blending as the basis for a systematic approach to discourse analysis aimed at improving modern communication strategies in educational contexts. He connects metacognition and intention while challenging linguistic approaches in higher education such as lectures, objective tests, and textbooks. Learners develop conceptual categories as a blend of new ideas and common conceptual frames from typified past experiences. In some cases, *visualizing conceptualizing* may provide opportunities for matrices or mental spaces to interact in ways difficult to communicate verbally: "The model of conceptual blending provides a way of structuring visualizations that mirror the cognitive process" (2013, p. 10).

CONSILIENCE

Consilience, the unity or *jumping together* of knowledge, is a term referring to the linking of facts, fact-based theory, and causal explanations across disciplines. The term was drawn from the phrase *consilience of inductions*, introduced by the Cambridge scholar William Whewell in 1840 to describe a scientific method by which the colligation of facts and convergence of various types of evidence results in the strongest scientific conclusions. Consilience did not reach prominence, however, until it was resurrected and expanded in the 20th century by evolutionary biologist Edward O. Wilson. Based on Charles Percival Snow's 1959 lecture explicating two divided academic cultures, the humanities and sciences, Wilson advocated for the erasure of the *territorial* lines between disciplines in favor of cooperative exploration; in other words, consilience, the unification of scientific and humanistic knowledge. Although Whewell's idea of the consilience of inductions sparked much debate among philosophers of science, Wilson's conceptualization of consilience has generated even more widespread attention and controversy.

Consilience as Scientific Method

In 1840, the English philosopher and historian of science William Whewell wrote a two-volume synthesis of science titled *The Philosophy of the Inductive Sciences, Founded Upon Their History*. In the second volume, Whewell introduced the phrase *consilience of inductions*, which he used to describe the phenomenon of altogether different classes of fact jumping together at the same point, resulting in the establishment of the *best* scientific theories. Whewell noted that the most monumental scientific discoveries were better explained by the colligation of distant facts and observations than by individual suppositions, even those constructed for the specific purpose of explaining the phenomenon. In following, Whewell argued then that the theories with the greatest explanatory power are consilient—the results of the greatest unification of knowledge.

Whewell acknowledged that the reality of science is that facts are not framed all at once; rather, theories are generally added to over time, with various advances and subsequent research. Consilient theories are those which subsequent suppositions serve to simplify and harmonize; ones that become even more coherent as they are extended. Theories which are not consilient become more complex and unmanageable as they are added to. Consilience, therefore, characterizes theories which represent a test of necessary *truth* and have a tendency toward simplicity and unity while maintaining deductive strength.

At its core, the consilience of inductions suggests a scientific method. Put simply, the consilience of inductions is the idea that multiple sources of evidence cohering to the same conclusion strengthen that conclusion. The strongest consilience is provided when the methods used to produce the evidence are completely or vastly different, as is generally the case when data are gathered by different disciplines with their own unique research techniques. In other words, the fewer characteristics shared by evidence producing the same conclusion, the more confident researchers can be of that conclusion, even when one source of evidence is less reliable than the others. The consilience of inductions as a method for achieving confidence is particularly important to

disciplines or research areas in which experimental research is not possible (e.g., evolutionary biology/psychology and intimate partner violence research). When experimental evidence is lacking, multiple sources, diverse evidence, and various research strategies converge to form *consilience arguments* used to support causal inferences drawn from nonexperimental data and to rule out competing explanations.

An example of this was presented by Kwok Leung and Fons J. R. van de Vijver in their discussion of epidemiological research. As they note, epidemiologists generally follow the methods of Whewell's consilience of inductions, primarily because experimental data are nearly impossible to gather, since assigning study participants randomly to treatment and control groups is unethical (i.e., you cannot introduce an epidemic for research purposes). As such, Leung and van de Vijver outlined the four criteria epidemiologists rely on to draw causal inferences from nonexperimental data: (1) rule out alternative explanations based on effect size (the strength of association between cause and effect); (2) establish temporal sequence—cause preceding effect—to rule out alternative explanations; (3) consistence, a consilience criterion referring to replicable effects across different populations and in different circumstances; and (4) coherence, another consilience criterion referring to the absence of conflicting evidence for proposed causal relationships.

Consilience of Academic Cultures

During the 1959 Rede Lecture at the University of Cambridge, C. P. Snow argued that intellectual life, particularly in the West, was divided into two opposing cultures, the sciences and the arts/humanities. He cautioned that such a division limits our collective ability to solve the world's problems. Snow later suggested the creation of a third culture, comprised of scholars across various disciplines who share an understanding of the sciences; in particular, biology, which as he suggested was the least exact of the hard sciences and thus open to the most interpretation.

In 1998, as a response to the division in academia outlined by Snow, Edward O. Wilson

published *Consilience: The Unity of Knowledge*. Wilson proposed consilience on a much broader and more ambitious scale than Whewell did, defining consilience as the unification of knowledge and the key to erasing the divide between the humanities and sciences. To Wilson, the pursuit of consilience represents the ultimate academic and intellectual challenge, the result of which will be an understanding of human nature with a higher degree of certainty than any discipline could produce on its own. Cooperation between the humanities and social sciences and equal contribution from all disciplines and specialties will increase the diversity and depth of knowledge, and give purpose to intellectuals (i.e., the pursuit of consilience). Wilson further addressed Snow's assertion that division limits the ability to solve the world's problems by framing consilience as the only way to confront the two foremost problems facing humanity in the 21st century: overpopulation and environmental destruction.

Wilson's conceptualization of consilience has received a great deal of criticism, particularly by scholars in the humanities who take issue with Wilson's assertion that establishing or refuting consilience is only achieved through methods developed in the natural sciences. As Wilson argued, the success of the natural sciences is in fact due to scientific reductionism. Opponents argue that scientific knowledge can be equally informed by humanistic study, and that methodological favoritism promotes inequity as opposed to a true alliance between the humanities and sciences. Fueling this argument is the fact that a large portion of the work toward consilience has been undertaken by scholars examining aspects of the humanities from scientific perspectives. An example of one of the few exceptions is the work of Jonah Lehrer, who contends that works of visual, musical, and culinary arts revealed truths about how the brain functions decades before these truths were obtained through reductionist scientific methods. To illustrate, Lehrer offers the early 20th-century novel *In Search of Lost Time* by the French novelist, critic, and essayist Marcel Proust (1871–1922). Lehrer argues that Proust constructed a model of the workings of memory seemingly consistent with the findings of recent scientific studies,

conducted over 100 years after the publication of Proust's novel.

Another area of controversy regarding consilience is the placement of the social sciences, which includes disciplines such as sociology, political science, psychology, and communication. Wilson acknowledged social sciences as a separate entity from the humanities and natural sciences but argued that the social sciences will divide themselves between the natural sciences (becoming continuous with biology, in particular) and the humanities, a process he states has already begun. Wilson does not suggest these discipline will disappear, only that they will exist in a radically different form. Evidence demonstrating Wilson's prediction can be found in many social science disciplines or subdisciplines. Examples include the convergence of sociology and biology (led by Wilson himself) into *sociobiology*, and the convergence of communication and biology into *communibiology*. Despite these convergences, there remain strong opponents who argue that the social sciences should represent a third distinct academic culture and not be relegated to the natural sciences or the humanities. Jerome Kagan presented such an argument against consilience and in favor of three academic cultures. Kagan outlined how the assumptions, terminology, and contributions of each of the three cultures are unique. As such, the contributions of each culture cannot be applied to any other culture, because the sources of evidence are so vastly different.

COSMOLOGY

The domain of cosmology is nothing less than the universe (or cosmos) at large, meaning everything that has, has had, or will have an existence, whether space, time, matter, or energy. In this all-embracing sense, cosmology goes far back in time in the form of mythological and philosophical speculations. What is far from obvious is that the universe can also be described and understood by means of observations related to scientific theories, but this is a late recognition which only bore fruit in the 20th century, especially after physicist Albert Einstein in 1915 promulgated the fundamental field equations that still serve as the theoretical basis of the modern understanding of the universe. Cosmology as a recognized scientific discipline only dates from the 1960s, when the big bang theory, so-called, won broad acceptance, and since then the standard big bang model of the universe has developed into a highly advanced science supported by sophisticated observations and experiments. Nonetheless, cosmology in the early 21st century is still a science in progress, and the standard model is challenged by several alternative views of the universe. In what follows, the development of cosmology is traced from the formulations of Isaac Newton, which were based on the heliocentric system of Copernicus put forth in the 16th century. The entry continues with an account of the 19th-century advent of astrophysics following the invention of spectroscopy; the theory of thermodynamics and the dispute between the proponents of the steady-state and the entropic heat-death hypotheses of the universe; and in

the 20th century until the present day, the model of the expanding universe and its confirmation with the discovery of the nebular red shift, lending support to the *big bang* theory of the universe's origins. The entry concludes with a review of the current consensus and the enigmas posed by dark matter and dark energy.

The Newtonian Universe

During the first half of the 17th century, an increasing number of astronomers adopted the Copernican world system, formulated by the Polish astronomer and mathematician Nicolaus Copernicus (1473–1543), with the Sun situated in the center of the universe and the Earth degraded to one planet out of six. Far outside Saturn, thought to be the outermost planet, resided the multitude of stars, about which practically nothing was known. How far away were the stars and how many were there? Did they all have roughly the same distance from the Sun, or did they stretch indefinitely out in endless space? The new cosmological system that emerged in the early 18th century owed much to Isaac Newton's mechanical physics, as presented in his masterpiece *Principia* from 1687. Not only were Newton and his contemporaries able to estimate the distances to the nearest stars, but based on Newton's universal law of gravitation, they also formulated a new cosmological model which would survive for about two centuries.

According to this model or worldview, space was infinite, uniformly filled with stars, and governed by gravitational forces. However, Newton and a few other natural philosophers vaguely realized that even with an infinite number of stars the universe would slowly become unstable and eventually come to a catastrophic end by collapsing upon itself, a scenario they considered to be unacceptable. The so-called *gravitational paradox* was only investigated in detail at the end of the 19th century when the German astronomer Hugo von Seeliger proved that a homogeneous and infinite stellar universe could not be brought into agreement with Newton's law of gravitation. Still, Seeliger's conclusion was not generally considered a serious problem for the Newtonian worldview. One way to escape the gravitational collapse

problem was to introduce a slight change in Newton's law at very large distances and another was to keep the law intact but postulate a *hierarchical universe* with a particular inhomogeneous distribution of stars.

In any case, the great majority of astronomers disregarded cosmological questions of this kind, which they saw as speculative and scarcely scientific. In the spirit of positivism, they argued that only the observed part of the universe belonged to science proper and that this part was limited to the myriads of stars contained in the Milky Way galaxy, to which our solar system belongs. The American fin-de-siècle astronomer Simon Newcomb admitted that space might be infinite and even populated with an infinity of stars and nebulae, but he added that this was merely a philosophical hypothesis which the scientific astronomer could safely ignore. Cosmology in the grander sense of the term—the study of the universe in its totality—was widely looked upon with suspicion and cultivated by only a minority of astronomers and physicists. After all, the universe as a whole is not observable, and according to the norms at the time science was concerned solely with what can be observed.

Astrophysics and Thermodynamics

Before the mid-19th century, the term *astrophysics* was close to being an oxymoron. After all, how could one possibly know about the physical constitution of the stars, not to mention their chemical composition? The invention of spectroscopy, the central technique of the new astrophysics, would entail a profound transformation of astronomy and in the long run, of cosmology. It was known that the observed wavelength of a light signal increases (shifts toward the red end of the spectrum) with the relative velocity of the source, and by the 1880s astronomers using the spectroscope were able to detect the *red shift* of stars and in this way to determine their radial velocities. In the 1910s, the American astronomer Vesto M. Slipher discovered the analogous red shift effect for nebulae, a discovery that turned out to be of momentous importance to cosmology. However, the cosmological interpretation of the nebular red

shifts—that they indicate an expanding universe—only became clear at about 1930.

The theory of thermodynamics was based on two fundamental laws of which the first was energy conservation and the second was that the entropy of a closed system inevitably increases. According to the German physicist Rudolf Clausius, one of the founders of thermodynamics and the inventor of the concept of entropy, the two laws were valid for the universe as a whole. Since entropy is a measure of a system's lack of order and organization, it followed that in the distant future the world would irreversibly dissolve into an eternal state with no structure and no life. The world would still exist, but it would be a dead world. The pessimistic prediction of a global *heat death* gave rise to a 40-year-long cosmological debate that involved some of the leading philosophers, theologians, and social critics of the late Victorian era. Reluctant to deal with concepts as metaphysical as the universe and its entropy, almost no professional astronomers took part in what has been called the *entropic controversy*.

Opponents of the heat-death scenario not only found it absurd and philosophically offensive, but they also realized that it implied a universe with a beginning in time and might therefore suggest a supernatural creation. The controversy over the cosmological implications of the second law was an integral part of the more general ideological struggle associated with the rise of materialism, atheism, and socialism as alternatives to traditional ways of conceiving nature, culture, and society. Among the participants were the philosophers Herbert Spencer and Friedrich Nietzsche, and communist pioneers such as Friedrich Engels and Louis-Auguste Blanqui. Although the controversy was more ideological than scientific, it concerned the development of the universe as a whole and as such, it was truly cosmological. Scenarios somewhat similar to that of heat death are still parts of modern cosmological theory.

20th-Century Observations

Observational cosmology in the early part of the 20th century was much concerned with the enigmatic spiral nebulae and their relations to the

Milky Way system. Harlow Shapley (1885–1972) and some other leading astronomers held that the material universe was essentially made up of one enormous galaxy, our Milky Way, with the nebulae being located in the remote parts of the Milky Way system. Other astronomers were in favor of the idea of an *island universe* first suggested by the philosopher Immanuel Kant in a work of 1755. According to this hypothesis, the spiral nebulae were independent galaxies far away from the Milky Way and approximately of the same size and structure. The debate between the two rival views of the universe was only settled in 1925 when Edwin Hubble at the Mount Wilson Observatory succeeded in measuring the distance to the Andromeda Nebula to be about 1 million light-years. With Hubble's discovery, the island universe theory was vindicated, and the nebulae became recognized as galaxies.

A few years later, Hubble (1889–1953) turned to a spectroscopic research program to find a relationship between the distances of the galaxies (r) and their red shifts. In a famous paper of 1929, he established from observations a linear relationship between the two quantities. Interpreting the red shift as an apparent radial velocity (v), he found that $v = Hr$, in which the constant of proportionality H is known as the *Hubble constant*. For the most distant of the galaxies in his data set, Hubble found that it receded from the Earth with a velocity of about 1,000 km/s. Thus, it seemed that all spiral nebulae or galaxies moved away from the Earth with recessional velocities increasing with their distances. Reluctant to go beyond observations, however, Hubble did not conclude from the $v = Hr$ law that the universe expands or that the galaxies actually move apart from each other. In fact, he never unambiguously supported the idea of an expanding universe of which he is often considered the father. Although his paper of 1929 is today hailed as a revolution in cosmological thought, this was not how the cautious Hubble looked upon it. Until his death in 1953, at a time when the expanding universe had long been accepted, he remained a skeptic, arguing that a static universe was still a possibility that could not be ruled out observationally.

Static and Expanding Models of the Universe

Shortly after having introduced his general theory of relativity, a new theory of gravitation that would come to replace Newton's, Einstein applied it to the universe at large. His cosmological theory of 1917 assumed a finite yet unbounded space uniformly populated with stars. Although this was not possible within the framework of Newtonian physics and Euclidean geometry, the space of Einstein's universe was positively curved, like the surface of a sphere. The idea of non-Euclidean curved space goes back to the 1830s but was for a long time considered a mathematical curiosity of no relevance to astronomy or physics. Einstein was not the first to apply curved space to cosmology, but he was one of the first to do so and by far the most important.

In order to secure a static, noncollapsing universe, Einstein added to his gravitational field equations an antigravity term called the *cosmological constant*, which he found to be necessary but eventually abandoned. Being static, the closed Einstein universe had no beginning in time and no end. Throughout the 1920s, a small group of physicists, astronomers, and mathematicians investigated the Einstein model, which they found to be satisfactory but far from perfect. One of the problems was that it could not account for the mysterious nebular red shifts found by Slipher.

Einstein thought, erroneously, that his 1917 model was the only realistic solution to the cosmological field equations. Although the Russian physicist Alexander Friedman proved in 1922 that there were solutions corresponding to expanding and other evolutionary models, his brilliant insight was ignored. The same was the case with an important paper of 1927 written by the Belgian physicist and Catholic priest Georges Lemaître, who independently of Friedman predicted an expanding version of the Einstein universe. Moreover, Lemaître demonstrated that the red shifts of the spiral galaxies could be explained as an effect of the expansion of cosmic space. In fact, he derived theoretically the linear Hubble law 2 years before Hubble presented it as an empirical law. Alas, the works of Friedman and Lemaître

were only recognized in 1930, when Arthur Eddington in England, Willem de Sitter in The Netherlands, and a few other prominent astronomers concluded that the static universe had to be replaced by an expanding one. Only then was Hubble's red shift-distance relation from the previous year interpreted as evidence for an expanding universe.

By the mid-1930s, the expanding universe was accepted by a majority of professional astronomers and physicists, but outside the circles of avant-garde scientists, the theory met with considerable opposition. The notion of an expanding universe might seem contradictory, for how can the universe—which comprises everything—become bigger and bigger? If it expands, what does it expand into? A minority of astronomers wanted to retain the more comprehensible static universe and consequently developed alternative hypotheses to account for the Hubble relation on which the expanding universe theory relied. For example, the red shifts could be explained on the *tired light* assumption that galactic photons gradually lost energy on their journey through space. For a while, the static alternatives were taken seriously, but since about 1950 they have been generally considered outside of mainstream science.

Big Bang Versus Steady State

One might believe that with the acceptance of the expanding universe followed the acceptance of a universe with a beginning time, on the grounds that if the universe expands continually there must have been a time in the past at which its size was zero or close to zero. As illustrated by the historical development of cosmological theory, however, a universe of finite age is not necessarily a consequence of an expanding universe. For example, Lemaître's model of 1927 had no definite beginning but evolved slowly from a preexisting and potentially unstable spherical Einstein universe. The audacious hypothesis of a universe with an origin in a small and very compact state was introduced by Lemaître in a paper of 1931, which marks the beginning of *big bang* cosmology. The Belgian cosmologist suggested that many billion years ago, all matter in the universe was concentrated in a primordial, highly radioactive body with a density of the same

order as an atomic nucleus. Space and time did not yet exist, but only emerged with the radioactive explosion of the hypothetical proto-universe or *primeval atom*, as Lemaître called it.

This first big bang model attracted much public interest but was received with reservation by most astronomers and physicists, who either ignored it or rejected it as hopelessly speculative. The idea of a universe that had somehow been created a finite time ago was considered quite radical, and through the 1930s it was accepted by less than a handful of cosmologists. The reason was not only the conceptual novelty of Lemaître's primeval-atom hypothesis but also that there was no empirical evidence that clearly supported it. It was only in the late 1940s, with the pioneering work of the Russian-American nuclear physicist George Gamow, that the big bang hypothesis was developed into a viable physical theory of the early universe.

With little or no inspiration from Lemaître, Gamow assumed the initial state of the universe to consist of a hot and highly compressed soup of neutrons. From this scenario, he and his collaborators tried to calculate how nuclear reactions would produce hydrogen and helium nuclei, and eventually all the nuclei of the known chemical elements. Gamow hoped to explain the observed cosmic abundance of elements, but although he succeeded with respect to helium it proved impossible to account for the formation of heavier elements. Nonetheless, Gamow's theory of the early universe attracted much interest, if more from nuclear physicists than from astronomers. During the period from about 1948 to the early 1960s, Gamow was the chief exponent of what came to be known as the hot big bang model.

The basic idea of a universe evolving in accordance with the equations of general relativity and with a past completely different from the present state was not generally accepted in the 1950s. According to the rival theory proposed in 1948 by three young Britons (Fred Hoyle, Hermann Bondi, and Thomas Gold), the universe had existed in approximately the same state for an infinity of time and would remain in the same state for another infinity of time. On a large scale, the universe satisfied the *perfect cosmological principle* of uniformity with respect to both space and time. Since the three physicists accepted the expansion of space, they had to postulate continuous

creation of matter in order to keep the mass density of the universe constant.

The steady-state theory, as it was called, was fundamentally different from the class of evolution theories based on general relativity, whether of the big bang type or not. From a methodological point of view, it was attractive because it resulted in a number of sharp and testable predictions, but it was also controversial because of its postulate of matter creation which contradicted the authoritative law of energy conservation. The protracted controversy between the two rival views of the cosmos was primarily of a scientific nature, but it also involved a heavy dose of philosophical issues. Which of the two main conceptions of the universe was the most scientific, and according to what criteria? The Austrian-British philosopher Karl Popper's ideas about falsifiability were used by Bondi and others to suggest that the steady-state theory was methodologically superior to the class of big bang theories. Among the philosophers of science who entered the debate were prominent figures such as Stephen Toulmin, Rom Harré, Adolf Grünbaum, and Norwood Russell Hanson.

Religion too was an element in the controversy. Whereas opponents of the big bang theory intimated that it was apologetic, a scientific version of Genesis, in Christian circles steady-state cosmology was widely associated with atheism. If there were no beginning of the universe, it might seem that there was no need for a divine Creator. The rival cosmological views also became part of the ideological battlefield in the Cold War era. In the Soviet Union, and later also in communist China, big bang models came to be seen as politically suspect and contrary to the atheistic worldview of Marxism-Leninism. Nor was the steady-state theory considered acceptable on such grounds: Although it posited no cosmic beginning, the continuous creation of matter was rejected as politically incorrect by zealous Communist Party ideologues.

Relativistic Standard Cosmology

The steady-state theory led to several sharp predictions which could be tested observationally, such as the curvature of space and the rate of expansion of the universe. For a long time,

however, observations were too uncertain to rule out the theory defended by Hoyle and his allies. The new science of radio astronomy promised to fare better and generally suggested that we do not live in a steady-state universe. But again, the results from radio astronomy did not amount to an unambiguous refutation of the theory. The point of no return came only in the mid-1960s with the discovery of the cosmic microwave background radiation, which agreed perfectly with the big bang theory but was inconsistent with the rival steady-state theory.

As early as 1948, two of Gamow's collaborators, Ralph Alpher and Robert Herman, had predicted a cosmic background of photons created in the early phase of the universe, but it took until 1964 before the radiation was serendipitously discovered. Shortly thereafter, physicists at Princeton University realized that the microwave background provided decisive support for the big bang, whereas it was incompatible with the steady-state theory. At about the same time, measurements of the cosmic abundance of helium led to the same conclusion. Thus, by the late 1960s, the theory proposed by Hoyle, Bondi, and Gold was no longer a viable alternative to the now victorious big bang theory based on general relativity and nuclear physics.

A few years after the discovery of the cosmic background radiation, there emerged a consensus view that the relativistic big bang theory was the one and only foundation of scientific cosmology. Although alternatives did not disappear, they were marginalized. At the same time that cosmology became cognitively institutionalized, it achieved a social institutionalization that made the subject a full-time occupation rather than a part-time hobby for astronomers and physicists. The field was increasingly integrated into university departments, and courses and textbooks on cosmology became common. For the first time, students were taught standard cosmology and brought up in a research tradition with a shared heritage. The publication in 1970 of James Peebles's *Physical Cosmology*, the first-ever textbook with this title, marked the beginning of a new and progressive development.

Whereas cosmology had earlier been a subfield sandwiched between astronomy and physics, it now aspired to become a scientific discipline in its

own right. With the professionalization and status as a respected field of science, there followed the exclusion of philosophers and amateur scientists, a development in stark contrast to the situation during the 1950s. Moreover, the national differences that had characterized earlier cosmology—big bang theory being American and steady-state theory British—also disappeared. By 1970, cosmology had become truly international, if not yet forming a scientific community.

Dark Energy and Other Surprises

The cosmological standard model in the 2020s is still a big bang universe governed by general relativity, as it was in the 1970s. And yet our present understanding of the universe differs significantly from the model favored 50 years ago, which was a universe with decreasing expansion rate, zero cosmological constant, and made up of ordinary matter in the form of atoms and their constituent particles. The cosmological constant (symbol Λ , lambda), which Einstein introduced in his static model of 1917, was since about 1930 considered to be a mistake (i.e., $\Lambda = 0$) and ignored by most cosmologists until it unexpectedly returned at the end of the century.

Observations from 1998 of distant supernovas showed that the rate of cosmic expansion is not decreasing, but increasing. We live in an accelerating universe. To account for the blowing up of space revealed by observations, physicists reintroduced the repulsive cosmological constant as a measure of the energy content of empty space, so-called *dark energy*. Although this strange form of self-generating energy has not been directly observed, it is generally believed that it fills all of space and dominates the fate of the universe. If the picture is correct, dark energy will cause the universe to expand indefinitely and at a still greater rate, meaning that in the far future it will consist almost entirely of lifeless empty space filled with dark energy. The heat-death scenario discussed in the late 19th century has returned, if in a different form.

As the modern universe is characterized by a large amount of dark energy, so is it characterized by an almost equally large amount of so-called *dark matter*, a concept going back to the 1930s but substantiated only some 40 years later from

observations of the rotation of galaxies and other evidence. As the name indicates, dark matter is a hypothetical form of invisible matter which acts gravitationally but not electromagnetically. Whatever dark matter is, it is entirely different from the ordinary matter consisting of protons, neutrons, and electrons, which makes up only 5% of the mass of the universe. The most recent data from 2019 indicate a mass distribution of 71% dark energy and 24% dark matter. Yet another discovery of momentous cosmological importance concerns the cosmic microwave background, which since 1989 has been explored by means of satellite experiments. The data from these and other experiments have revealed small variations in the energy density of the otherwise uniform radiation, from which cosmologists have derived a wealth of information about the very early universe. The many measurements from satellites and other experiments have led to a surprisingly precise determination of the age of the universe, which by 2019 was believed to be 13.787 billion years, with an uncertainty of only 0.020 billion years.

The Consensus Model and Its Critics

The standard model established in the early years of the new millennium is also known as the Λ CDM *model* because it relies on the cosmological constant (Λ) and cold dark matter (CDM), the term *cold* meaning that the hypothetical dark matter particles move relatively slowly. The model has been very successful insofar as it has an impressive explanatory and predictive record, and for this reason it is the accepted framework for mainstream work in theoretical and observational cosmology. It is generally admitted, however, that there are flaws or at least unsolved problems in the Λ CDM theory. One of them concerns dark energy, namely that the observed value of the cosmological constant differs dramatically from the one calculated on the basis of quantum mechanics. The persistent failure in detecting the particles constituting dark matter is another serious problem.

Whereas the standard model assumes the universe to have come into existence with the big bang, some physicists argue from theories of quantum gravity, such as string theory, that our universe was preceded by a *pre-big bang universe*

stretching infinitely back in time. The collapse of this earlier universe gave rise to a *big crunch* out of which the big bang emerged. These theories are to some extent mathematical speculations, but in principle and possibly also in practice they are empirically testable. The same is the case with the controversial and much-discussed *multiverse* hypothesis from about 1990, the claim that there exist a huge number of other universes in addition to the one we inhabit. The other universes may be causally separated from ours and may have different natural constants and physical laws, which makes the multiverse hypothesis even more controversial.

Although the standard Λ CDM model functions as a kind of paradigm in the sense meant by the historian of science Thomas Kuhn, it is not beyond criticism. While it has received little attention from philosophers and sociologists of science, a minority of physicists and astronomers have expressed strong dissatisfaction with the current state of cosmology. One of them is the prominent South African cosmologist George Ellis, who has warned against metaphysical tendencies in parts of modern cosmology such as the belief in a spatially infinite universe. According to Ellis, infinities do not belong to science. Other critics, among them the astrophysicists Robert Sanders and David Merritt, focus on what they consider to be the unfounded postulate of dark matter, a central element in the standard model. In part from philosophical positions, they suggest that the current cosmological paradigm is a dogma that prevents innovative thinking and a necessary revision of how to understand the universe. A paradigm shift is therefore needed. However, the critical voices have not seriously shattered the cosmological community's general confidence in the standard Λ CDM model.

CYBERNETICS, 20TH CENTURY

At the beginning, cybernetics was a wide-ranging interdisciplinary effort spurred on by the mathematician and philosopher Norbert Wiener and a group of scientific colleagues with the intent to study communication, feedback, and control in biological, physical, engineering, and social systems. Feedback and circular causality associated with it was key to the investigations of this group so that the concept moved along from the simple

aspects of engineering regularities such as thermostats and regulators for steam engines and other mechanisms to the subtleties of the feedbacks in muscle/eye coordination in organisms, and the deeper subtleties of the regulation of speech and logic and cognition in the act of its production. Starting with the development of core themes in the emerging field of cybernetics, the entry continues with an account of the development of mathematical models and a discussion of reference and self-reference and their connection with language. An explanation of Gödel's Theorem follows, and the entry concludes with discussion of autopoiesis and the self-producing nature of living systems.

Key Themes

The theme of feedback and circularity widens and deepens as it is studied by cyberneticians and encompasses systems maintaining their structure in terms of their own action in a world of change. The original Macy Conferences on Circular Causality included all these themes, and with the inclusion of mathematicians of the caliber of Wiener and John von Neumann, the discussions ranged over the implications of computers, Turing machines, self-reproducing automata, information, logic, the beginnings of automation, and the social consequences of automation. Warren McCulloch and Walter Pitts joined the group and lived in the long wonder of how it can be that mind, logic, and thought can be interwound with the workings of the brain and with the properties of networks and circularly interconnected systems. McCulloch wrote papers with titles like "What is a Man that he may know a Number and what is a Number that it can be known by a Man?" With the inclusion of the anthropologists Gregory Bateson and Margaret Mead, the discussion extended itself to questions of how individuals and societies worked together and how the world/worldview of an individual is shaped by their society and how their society is shaped by the individual. This theme of circularity becomes the always-changing basis for the depths of cybernetic study.

The original discussions of cybernetics were deeply related to the meaning of that term as embodied in the Norbert Wiener's title for his book *Cybernetics—or Control and Communication in*

the Animal and in the Machine. The book was published in 1948 and was Wiener's summary of interdisciplinary discussions that had begun 10 years earlier, prior to World War II. These discussions were influenced by the war and by such problems as understanding computers as they were emerging, analog and digital, and understanding how to predict and control aircraft and navigation processes. The discussions moved across fields including physics, biology, and engineering. The initial direct problems of steering a gun, a ship, or one's own body directly or in the operation of a prosthesis led Wiener and his group to study the properties of feedback and the circular processes associated with it and to hypothesize this area of feedback and circular causality as fundamental in biology, engineering, and human planning. Concomitant with feedback in this sense is the sort of communication that supports it, and so large themes of communication, information and stability, instabilities and the possibility of homeostasis arrive in the core of cybernetics. The interdisciplinary discussion was fed by streams from all its participants and did not stay at the level of mechanical or direct physical-biological actions.

Pioneers in Cybernetic Thinking

The question of the influence of communication and feedback for the action of societies and groups of individuals was just as important and indeed was and is a central concern for cybernetics. Once communication and information became a theme, questions of quantitative measurement arose, and one finds the work of Claude Shannon speaking to that. Questions of mind arise, and one finds the work of McCulloch and Pitts speaking to that. As soon as the social level enters the discussion, the role of the observer is present and can be found in Wiener's discussions of language and society in his book. It was a major theme for Wiener to see the possibilities of automation and its influence on society. Again the influence of the war years is crucial in the history of these developments. Consider the role of control and communication in relation to secret communications, the coding in such devices as the Enigma Machine and the key role of early computers, recursion, and the analysis of languages in the decoding, all for the

sake of prediction and control in the war effort. At the same time, the message structures of nationalistic propaganda were in battle with these same forces, and nuclear technology was under development—all for the sake of manifest levels of control and survival. There is no way to separate technology from the social structures that it affects. The themes of feedback, communication, and control are integral to the understanding of interactions at all levels. All these themes are now upon us again and always as we watch and participate in the influence of worldwide computer networks, the rise of so-called artificial intelligence and the continuing need to find ways through the complexities of human relationships and decisions in the worlds created by our own recursions.

In the wake of the original Macy Conferences, Heinz von Foerster became an eloquent spokesperson for the themes of cybernetics. Others, such as Ross Ashby, arose and wrote books on the principles of the subject. New explorers such as Stafford Beer, Gordon Pask, Humberto Maturana, Francisco Varela, Ernst von Glasersfeld, Ranulph Glanville, and Annetta Pedretti came forward. The field continues its wide thematic approach. Much of modern thought, computer science, systems thinking, complexity thinking, studies in chaos theory, logic, and ideas about reflexivity and interdependence have their origins in cybernetics.

Second-Order Cybernetics

A significant shift in the definition of cybernetics occurred with Mead's injunction that the methods of cybernetics should be applied to cybernetics itself, and with von Foerster's naming of this new cybernetics as *second-order cybernetics*. Second order was to be the cybernetics of observing systems, where the system was its own observer, its own cognizer, just as a human being can be an observer of themselves, and just as language can discuss and refer to language itself.

At the concept of the second order, we arrive at closure. It should be noted that the cybernetics of the second order had been practiced by cyberneticians from the beginning. Nevertheless, it is a significant shift of viewpoint to name this way of thinking and being. Having come to second-order

cybernetics and its inevitable reflexivity, we are now prepared to explore the many ramifications of the cybernetic concept.

One way to understand the emergence of second-order cybernetics is to see it as completing a larger circularity, a feedback loop that includes Meaning and Form (form, syntax, logic, scientific explanation) in one whole:

Syntax gives rise to meaning.

Meaning gives rise to syntax.

In this characterization, the observer holds meaning and relationship, and the participation of individuals with one another and with their activities. These activities have form, pattern, syntax, and transferability that allow explanation and the possibility of interdisciplinary comparison. Meaning can always ask more and demand a larger context. There is a sense of the whole that consists in meaning and form in dialogue. It is at the level of such wholes that one can ask about the meaning of meaning or the nature of number or the role of consciousness in systems. This thematic relationship has always been present in cybernetics, but the emergence of a conscious statement of second-order cybernetics as a form of cybernetics has made the difference between cybernetics as a commentary on science, engineering and computation and social structure, and cybernetics as a true transdisciplinary activity.

It is at the level of shared pattern (the level of concept) that we find our commonality and the possibility of mutual participation that is key for cybernetics and other transdisciplinary studies. Just so it is at the level of shared and understood language that we find that commonality. To begin to understand language is to begin to understand the nature of pattern and the role of cybernetics.

Mathematics, Language, and Cybernetics

It must be pointed out that mathematics is another kind of languaging, letting an observer play with symbols on paper without themselves seeming to appear on that paper. In the course of that play, the observer is involved and not separated from the actions in the seemingly separate world of the paper. The meaning that this activity generates

weaves a deeper world where the observer and their actions with paper or other media are inseparable from themselves.

The sorts of mathematical models that have been and are being used in cybernetics are as follows: mathematical logic, lambda calculus, Laws of Form, reflexive domains, Turing machines, mathematics of recursion, logical networks (as in the work of McCulloch and Pitts), general circularly interconnected networks that can model systems of all kinds—including graphs and general systems of graphs, and category theory. Recursions and cellular automata became widely studied after the 1960s, and some of these themes are of particular importance in cybernetics.

For example, Mitchell Feigenbaum discovered that there were universal properties in the real line recursion $x' = kx(1 - x)$. That such simple examples of feedback can have a wide applicability and increase our understanding of mathematics and nature is a puzzle for those interested in cybernetics from its ground up.

The properties of recursions such as $x' = kx(1 - x)$ are noteworthy *because this phenomenon places us squarely in between interpreting cybernetics in the second order and interpreting it in the first order*. If one looks into the mathematical and computational properties of a recursion, it may appear that one is only examining a technicality using a standard Western objective epistemology. This is not so, in that there is no necessary link between examining the mathematics of a recursion and one's assumptions about the nature of mind and the mind of nature. Nevertheless, one has the situation that the geometry of processes like $kx(1 - x)$ reveal great depths unsuspected prior to the mathematical experiment. Mathematics advances by observing its own productions. One way to understand this situation is to examine how, in handling recursions, the observer takes a role. Then we can look at intensities like $kx(1 - x)$ and ask about the role of the observer in such a study. In so doing, we confront the roles of awareness, distinction, and the participation of the observer in the production of reality.

We begin in language. We begin in the situation where language and metalanguage, language about language, are one.

Language = MetaLanguage

To live in thought and language is to live in dialectic and paradox, circularity, and feedback. This is the cybernetic beginning. From here it is natural to examine all that might lead to clarity and logic and science. How did it happen that we managed the regularities that we have actually managed? What is the role of reason in this fundamental circularity? From this reflexive place, we can see the source of cybernetic questions from beginning to end. And we can see how mathematical and symbolic structures play a key role in providing the glue that binds discursive, logical, and quantitative thoughts.

Cybernetics has a long history from interdisciplinary discussions of many instances of feedback, communication, and control to becoming self-conscious of its own aims and being willing to apply itself to itself. We have looked at the role of language, sign, and symbol for the understanding of understanding, the describing of describing. These produce domains of action that involve the creation of new language, new mathematics, and new approaches to praxis.

Distinction, Awareness, and Self-Reference

It is possible for a sign to stand for itself.

For example, a mark $< >$ can be regarded as a sign for the distinction that it makes between its inside and its outside.

The mark is a sign that stands for itself.

In his seminal work *Laws of Form*, G. Spencer-Brown takes the self-referential mark of distinction as a starting point and the equations

$$<><> = <>$$

$$<<>> =$$

as the expression of a calculus of indications. The first equation can be interpreted as the redundancy of calling the name of the mark by itself. If I wear a name tag, it is not necessary. The second equation involves regarding the sign $<>$ as an act of distinction or crossing. To cross from the unmarked state achieves the marked state: $<> = <>$. To cross from the marked state achieves the unmarked state $<<>> =$. The calculus of indications of Spencer-Brown is a

minimal formalism in the enactment of meaning and syntax.

Contraction of reference leads to the expansion of awareness.

Language, Reference, and Self-Reference

We can discuss describing through a simple language involving the digits 1, 2, 3 and their meanings as one, two, three. Consider the pattern of numbers below:

1

11

21

1211

111221

Each line is a description of the previous line. To see this, read the lines aloud. The second line says "one one" and that is a description of the first line. The third line says "two ones" and that is a description of the second line. The next line says "one two, one one," then "one one, one two, two ones," and so on. The full alphabet for this recursion is the set of numerals {1, 2, 3}, and these are alternately signs and elements of the description of a pattern. This *audioactive sequence* was extensively investigated by John Horton Conway and has many mathematical properties.

In the audioactive formalism, we have that $2x$ describes xx . Thus, 22 describes 22, and we arrive at self-reference in this small language. We can write $a \rightarrow b$ where the arrow denotes that " a describes b ." Then we have $2x \rightarrow xx$ and letting $x = 2$, we have $22 \rightarrow 22$.

We could begin with $gx \rightarrow xx$ and obtain $gg \rightarrow gg$ by substitution, but there is no given meaning for g or for the arrow $gx \rightarrow xx$. By generalizing the meaningful pattern $2x \rightarrow xx$, to an apparently meaningless pattern $gx \rightarrow xx$ (from meaning to syntax) we enter a wider domain of possible meanings (hence from syntax to wider meaning).

This is particularly so with the work of Alonzo Church and Haskell Curry on the Lambda calculus, since they generalize even further to the pattern $gx = F(xx)$ and then obtain a fixed point for

F by the substitution $gg = F(gg)$. In fact, they were motivated in this endeavor by the special case of $Rx = \sim xx$ where $\sim$ denotes negation in logic and AB denotes that “B is a member of A.” Then $Rx = \sim xx$ is interpreted to mean that *x is a member of R exactly when x is not a member of x*. This is the Russell set. We obtain $RR = \sim RR$, meaning that R is a member of R exactly when R is not a member of R. This is the Russell Paradox. The paradox asserts that negation can have a fixed point. In a cybernetic context, this is a viable possibility.

The route to self-reference we are discussing widens to a process I call the *indicative shift*.

Let

$$b \rightarrow B$$

denote a *reference of b to B*. You can take b to be a name for B.

The *shift* of this reference is denoted by

$$\#b \rightarrow Bb.$$

I am introduced to Mister B and my host says to me, please meet “b.” Being an attentive guest, I make an association of the name b with the appearance B and put them together in my mind. The next time I meet B, he appears to me as a Bb in the sense that the name comes right along with him. In my imagination, B has the name tag b on his lapel. I also have that name stored with a marker #b (made explicitly here but usually unsaid). The name #b is now pointing to my amalgam of B with his name. To examine your own process in this regard, think of the times you have encountered someone whose name you have forgotten. You find yourself attempting to reconstruct the links we have just described.

What does the indicative shift have to do with self-reference? Let M be the name of the shift. Then

$$M \rightarrow \#.$$

Shifting, we find that

$$\#M \rightarrow \#M.$$

The meta-name (#M) of the name of the shift refers to itself.

We rewrite:

I am the meta-name of my meta-naming process. and find a relative of the Heinz von Foerster sentence

“I am the observed relation between myself and observing myself.”

Begin the indicative shift at the most elemental point.

$$\rightarrow$$

This is an arrow from nothing to nothing. Nothing stands for nothing. The arrow is prior to names.

Apply the shift.

$$\# \rightarrow$$

There was nothing to shift.

Apply the shift again.

$$\#\# \rightarrow \#$$

And again.

$$\#\#\# \rightarrow \#\#\#.$$

Thus, we have

$$\rightarrow$$

$$\# \rightarrow$$

$$\#\# \rightarrow \#$$

$$\#\#\# \rightarrow \#\#\#.$$

At the third departure from the void, we find that self-reference has occurred.

Meaning arises from syntax in our understanding of the process that it connotes.

In the beginning there was no name.

The shift became the name of nothing.

The shift of the name of nothing became the name of the shift.

The shift of the name of the shift is its own name.

Here begins a cybernetics of the acts of distinction.

The self-reference of the indicative shift is more subtle than Two Twos. It involves the action of observing and it shows how the act of observing (and naming) turns around and names itself. We are aware of the realm of meaning for the observer and here we have begun steps into a syntax for the observer. The second order cybernetic loop of Meaning and Syntax must continue

into great richness before we can be willing to say that we have a cybernetics of observing systems.

May that happen in the course of time.

The Gödelian Shift

The indicative shift occurs in reference and naming in language and communication. A shift of this shift takes us to the key structures of Gödel's incompleteness theorem.

Kurt Gödel proved that no consistent formal system rich enough to handle number theory could be complete. Gödel showed that there are true theorems about numbers that the given formal system cannot prove.

Gödel produced a sentence that encoded a denial of its own provability. He devised a method to code each formula F in his system with a number $g = g(F)$ (the Gödel number) so that the formula could be uniquely decoded from its number. I will write $g \rightarrow F$ to denote that " g is the Gödel number of F ."

Now suppose that $F(u)$ is a formula with a free variable u .

For example $F(u)$ could be " u is a prime number." Let g be the Gödel number of $F(u)$. Then we can substitute g into $F(u)$ to obtain $F(g)$. This is a new formula with a new Gödel number, call it $\#g$. Then we have $\#g \rightarrow F(g)$. This is the "Gödelian indicative shift" of $g \rightarrow F(u)$.

$$g \rightarrow F(u).$$

$$\#g \rightarrow F(g).$$

Now the function assigning the number $\#g$ to the number g is an algorithm about numbers, just the sort of thing that Gödel's formal system L can talk about. Thus, we can have $\#$ as an element in the language of L .

Let $B(u)$ be a statement in L that asserts the provability of the statement with Gödel number u . Then $\sim B(u)$ asserts the unprovability of the statement with Gödel number u . And furthermore, we have a Gödel number for $\sim B(\#u)$, the statement that the formula with Gödel number $\#u$ is not a provable formula:

$$g \rightarrow \sim B(\#u).$$

Then making the shift, we have

$$\#g \rightarrow \sim B(\#g).$$

This shows that $\sim B(\#g)$ asserts the unprovability of the formula with Gödel number $\#g$. But that formula is $\sim B(\#g)$! This means that $\sim B(\#g)$ asserts its own unprovability.

If L could prove this formula, then L would be inconsistent.

We assume that L is consistent and conclude that it cannot make the proof.

But that is exactly what the formula says, and so $\sim B(\#g)$ is true but not provable in L .

We have sketched the proof of Gödel's incompleteness theorem and as you see, the Gödelian indicative shift is the key mechanism whereby self-reference is achieved to obtain a theorem that asserts its own unprovability. The self-reference is accomplished via the coding from texts to Gödel numbers, and so is protected from paradox. Here the pendulum swings from the meaningful arena of the indicative shift in the naming processes of ordinary language to the highly syntactical regions of formal systems.

The Gödel Theorem deserves to be seen as second-order cybernetics. Its content requires an observer and their understanding. The Gödel Theorem requires the rational comprehension of an observer of the formalism. In working with the final shifted equation

$$\#g \rightarrow \sim B(\#g)$$

we stand outside the formal system, understanding the meaning of the reference that makes $\sim B(\#g)$ state its own unprovability. We prove that L will produce a contradiction within its own syntax if L should produce a demonstration of $\sim B(\#g)$. We reason structurally about L through our relationship with L . We have access to the properties of the shift and an ability to reason about it that is not available to L .

We begin to understand how we as observers can be in intimate relation with a formal system. We can go forward into the classical and deep questions of the relationship of ourselves and machines (formalities, syntax). We return as always to the understanding that cybernetics studies the feedback loop of meaning and syntax and see this relationship anew.

Autopoiesis and the Meaning of Living Form

It has long been understood in cybernetics that one should think of living systems and indeed larger organizations such as societies, worlds, galaxies, and the universe herself as producing themselves out of their own productions in the contexts of those environments appropriate to such actions.

Even our simplest example of Two Twos produces itself out its own production, where that production is the meaning associated with the syntax. But in autopoietic models, we can begin to see how self-sustaining systems can arise from the circular interactions of a (e.g., molecular biological or social) given substrate. Circularity is a natural condition of process.

To be produced out of one's own productions is to be an *eigenform* of oneself. Look at how different thinkers have handled this notion and what wisdom they have given us. McCulloch wanted to know how the brain could find number and how number could find the brain. How does the brain produce concept from itself and from its environment? How does concept influence the brain? McCulloch and Pitts did pioneering work in taking symbolic logic to a domain for modeled neural processes. Their work comes down to the present day in neural nets and machine learning and all the matters of logic and computing. The fundamental questions are as mysterious as ever. Conceptual calculus is not identical to its formalism any more than second-order cybernetics is identical to the study of feedback and machines.

Others, such as Gordon Pask, have investigated language with geometry and networks and topological possibilities. Sensitive intelligences such as Humberto Maturana saw living processes directly in terms of the worlds those processes created in the course of producing themselves. An organism producing itself is continually reacting not to an outside world but to the perturbations of its context and stability by what we observers perceive to be its outside world. We as observers of that organism see more and see less than the organism itself. We see structure and limitation and properties of the environment. We have not the sight to be the world of that plant or animal. We have intuition from our own experience of being, but

that experience does not fully cross the gap between one of us and another. And so it is that cybernetics shows rather than directly says (compare Wittgenstein and Spencer-Brown) what can bridge the unbridgeable gaps of communication that are needed for us to produce ourselves from ourselves.

D

DATA AND PHENOMENA

Scientists often want to check whether their theories hold up in the face of results gleaned from observations and experiments. A natural thought might be to assume that when scientists check their theories in this way, they check their theories against the empirical data produced by observations and experiments. If theoretical predictions match the empirical data, then—one might think—that is good news for the viability of the theory in question, whereas if theoretical predictions conflict with the empirical data, that counts against the truth or adequacy of the theory.

James Bogen and James Woodward argued in 1988, however, that this natural thought is mistaken. Scientists do not check theories against empirical data directly, nor should they. Data are idiosyncratic in the sense that they are produced by the contribution of a variety of causal factors, including minute and practically untraceable influences besides the primary subject of research. High-level scientific theories, Bogen and Woodward argued, are not invoked to predict or explain the minute variations in data, but rather the stable and repeatable characteristics of phenomena that can be separated from irrelevant idiosyncrasies by data-to-phenomena reasoning. This entry explores the issues implied by that argument for the relationship between data and phenomena.

Consider a simple experiment to determine whether a coin is fair. The experimenter conducts

one hundred trials by flipping the coin and recording *heads* or *tails* for each flip. These records are the data. However, what is useful for checking whether the coin is fair is a summary statistic, for instance, the mean of *heads* throughout the hundred trials. A similar insight applies to significantly more complicated data. Thus, Bogen and Woodward argued that the sort of techniques and methods of inferential reasoning that scientists use to transform data into claims about phenomena are of significant interest for the epistemology of science in practice.

Explaining the Phenomena

Bogen and Woodward introduced an influential distinction between data and phenomena. For them, data provide evidence for the existence of phenomena. In contrast, phenomena provide evidence for theories. In their canonical 1988 paper, Bogen and Woodward emphasized that data cannot typically be predicted or explained by theory, whereas phenomena can. For the coin flip experiment, the hypothesis that the coin is fair neither predicts nor explains the outcome of any individual trial, but it does predict and explain the average number of heads over a long sequence of trials. Bogen and Woodward mentioned more sophisticated and realistic scientific examples to illustrate their distinction between data and phenomena. Their examples of data included photographs and records of a variety of detectors, while their examples of phenomena included types of

nuclear reactions and certain aspects of human cognition.

Bogen and Woodward discussed a simple example involving the melting point of lead. Repeated, sufficiently precise thermometer readings of a sample of lead at its melting point would produce measurements that differ slightly from one another—the data would have some scatter. Given certain assumptions about the causes of the scatter, one can reasonably estimate the true temperature of lead's melting point. As in the coin flip experiment, the mean value of the temperature readings is what is ultimately of interest for determining the melting point of lead—a value that Bogen and Woodward stressed may not actually coincide exactly with any of the individual readings. Scientific theories, they argued, provide high-level, systematic explanations only of phenomena and not of data. To explain the value of a data point, or of the values of a scattered data set, would seem to require a quixotic accounting of highly particular causal minutia. Typically, such explanations cannot be provided in sufficient causal mechanistic detail to count as *systematic* in the sense Bogen and Woodward intended. Regardless, such explanations are not what scientists usually seek to explain or predict with their theories. In contrast, to the capriciousness of data, phenomena exhibit stability and generality.

Challenges

Since Bogen and Woodward's original 1988 publication, other philosophers of science have raised several challenges to their arguments. A handful of these contentions are discussed below.

Portability of Data, Locality of Claims About Phenomena

Sabina Leonelli has invoked database curation practices in biology in order to challenge two main claims that she attributes to Bogen and Woodward. The first claim that Leonelli challenges is the idea that data are local in a manner that claims about phenomena are not. Since data are produced by particular causal processes that are specific to the context in which they were produced, one might think that they cannot directly have general evidential value. Rather, following

Bogen and Woodward, data serve as evidence for claims about phenomena, which in turn serve as evidence for general scientific theories. Their idiosyncrasies make particular data different enough across contexts to render them local in contrast to the stability and repeatability of phenomena. The particularities of a single temperature measurement may never be exactly repeated, but the melting point of lead itself is stable. Leonelli challenges this claim by arguing that suitably prepared data can travel beyond the specific context in which they were originally produced and indeed be put to evidential use elsewhere. For instance, in the biological sciences, data collected on a particular model organism may be useful to many different researchers focusing on different phenomena that can be studied via that model organism. By carefully extracting, labeling, and making data available for other researchers to search, database curators can help data *travel* and find new applications in diverse epistemic contexts. Thus, Leonelli argues that data need not always remain solely within the context of their provenance. So, while the idiosyncrasies of a particular datum may depend on the context-sensitive details of its provenance, suitably assisted scientists evidently sometimes repurpose data in diverse contexts without calling upon claims about phenomena as intermediaries.

The second claim that Leonelli challenges concerns the purported generality of claims about phenomena. She argues that in biological sciences claims about phenomena can be highly context dependent, and like data, require careful packaging in order to be put to use more broadly. For example, Leonelli highlights the diversity of crucial concepts and terminology that biologists use to characterize their phenomena of interest among adjacent research contexts. She describes how key terms such as *bud*, *pathogen*, and *cell wall* have different meanings to different research communities, and how the same phenomenon or entity (such as a virus particle external to the cell) can be associated with different terms. Leonelli argues that database curators need to also take such context-sensitive variety on the side of phenomenon identification and characterization into account when facilitating database searches and use. Claims about phenomena, Leonelli argues, are therefore not always *nonlocal* in the manner

that might be suggested by Bogen and Woodward. Leonelli agrees with Bogen and Woodward that claims about phenomena play a special kind of evidential role for which data are unsuitable, but she attributes this to their formulation as propositions (as opposed to the *marks* of data, like photographs or chart recordings) rather than to their special nonlocality.

Explaining Data

Greg Lusk has argued that Bogen and Woodward's insistence that scientists do not, and ought not, provide systematic theoretical explanations for idiosyncratic data misses interesting cases from science in practice that, he argues, do just that. According to Lusk, scientists do sometimes explain data as a way of identifying phenomena. His primary example involves a method that atmospheric scientists use to infer the concentrations of various gas species in the atmosphere. Electromagnetic radiation passing through the layers of Earth's atmosphere is absorbed by these gases in characteristic ways. Scientists collect data from that radiation on Earth's surface and process the data in such a way as to reveal the patterns the missing radiation leaves in the overall spectrum of the radiation. The phenomenon that these scientists are ultimately interested in is the distribution of atmospheric gases. To make empirically informed inferences about the distribution of gases from the spectra, they face a so-called inverse problem. Some gas species can interfere with characteristic absorption patterns of another species of gas. Without such interference, one might hope to infer the presence of a particular gas species in the atmosphere by noting the presence of its unique absorption pattern in the spectrum. However, the interference from other gas species ruins this tight correlation. The presence of a particular pattern in a spectrum thus leaves the atmospheric scientists with several possibilities for which combination of gases is responsible for it. To address this issue, scientists utilize a method called *retrieval*. In brief, retrieval involves calculating a variety of possible spectra using background knowledge about the distribution and concentration of atmospheric gases. Each of these possible spectra derives from a guess about what the actual gas concentrations are. Then, by using a

selection procedure that minimizes the difference between the real spectrum and the calculated one, taking into account relevant background knowledge, the scientists identify their best guess for the actual state of the atmosphere. Lusk argues that this is a case in which scientists explain data, and for good reasons. The spectrum is the data, and it is explained in the sense that a systematic derivation is provided for it. Lusk's argument for the systematic nature of the explanation relies on the fact that the atmospheric scientists effectively answer "what-if-things-had-been-different" questions about possible causal contributions to the spectrum. Answers to these counterfactual dependence questions are provided by the calculation of various plausible spectra, given the relevant background knowledge, which spectra are then used in the selection procedure to determine which atmospheric state to infer. Lusk suggests that not only is this case an example of the systematic explanation of data in scientific practice but also that the explanations in question play a crucial role in the identification of the phenomena of interest. Lusk also points out that the inverse problem of the sort involved in his atmospheric science case can be found in several other areas of science as well, such as geology, climatology, astronomy, medical imaging, and so on. Thus, he argues that the role of explaining data may be significantly more influential in scientific practice than Bogen and Woodward originally countenanced.

Noise

Bogen and Woodward distinguished the idiosyncratic causes contributing to data from the phenomenon of interest by describing phenomena as having stable and repeatable characteristics. In several papers, they characterize the idiosyncratic contributions to the causal production of data as *noise* or *error*. In light of this, one might wonder whether there are types of noise and/or error that are important to science in practice, which have stable and repeatable characteristics themselves. For instance, *shot noise* is a particular type of noise well-known to users of electronics. Photons or electrons, considered as discrete quanta, arrive at a detector shot by shot. Consider constructing an image using a CCD camera one photon at a time. The image would be *noisy*, and its clarity

would increase as more and more photons were added. Knowing that this sort of noise has this stable and repeatable characteristic—namely that it diminishes in a predictable and formalizable way—and that it has a theoretical explanation—in this case resting on quantum discreteness—is epistemically useful to scientists working with such detectors. This suggests that either there are some useful explanations of noise or that in some cases, the noise is (first) the phenomenon of interest.

Woodward (in his 2010 article for instance) emphasizes that scientists do not explain single data points. There may be some cases, however, in which a high-level explanation of even a single data point is both present and desirable in scientific practice. To take another example related to detector electronics—a spurious datum can be caused by a single high-energy cosmic ray passing through a detector. A high-level theoretical explanation of the influence of a cosmic ray on the production of data can be given, and the contribution of the *artifact* or *error* sufficiently characterized to warrant removing the affected datum from the main scientific analysis (unless the phenomenon under study is cosmic rays).

The Nature of Phenomena

Drawing a distinction between data and phenomena also raises questions about the nature of the phenomena. Following Bogen and Woodward, phenomena are supposed to be stable and repeatable across some range of contexts. They are immune to some idiosyncrasies that vary between such contexts, and they are not one-off events or flukes. But how do scientists identify phenomena or decide upon whether something counts as a phenomenon or not? David Colaço has argued that in addition to attending to explanations of phenomena, attention ought to be paid to how phenomena are characterized in the first place, and indeed how they are sometimes recharacterized in light of empirical research. Colaço's argument responds to the so-called mechanists in philosophy of science who have argued that phenomena are recharacterized in response to discrepant empirical results. For example, scientists may initially regard and represent what they ultimately deem to be multiple distinct phenomena under a single initial characterization. Colaço

contends that the mechanists mistakenly held that when characterization of a phenomenon faces discrepant results, scientists will recharacterize that phenomenon, for example, by splitting up what they regard as an inappropriately lumped characterization in response to the discrepant results. In contrast, Colaço argues that faced with such discrepancies, scientists suspend judgment regarding the initial characterization and pursue further research to investigate the discrepancies, rather than rejecting the characterization outright. Scientists do reject phenomena characterizations when faced with empirical results that are incompatible with those characterizations, such as when conditions supposed to produce the phenomenon of interest fail to do so.

Restatement and Defense

In 2011, Woodward explicitly revisited the arguments of Bogen and Woodward from 1988, providing clarifications and responding to some points of criticism that had been raised in the intervening years. Woodward clarified the scope of the argument about data and phenomena—rather than insisting on a sweeping generalization about what *always* or *typically* happens in scientific reasoning, he emphasized the desirability of paying attention to various kinds of reasoning from data-to-phenomena that are not as prominent in philosophy of science as one might expect given their centrality in scientific practice. In his reflections on the original argument, Woodward does still stand by the original position of Bogen and Woodward regarding explanations of data. In particular, Woodward continues to emphasize that scientists do not seek to provide such explanations both because the scientists do not need them and because such explanations would be impractical to furnish.

The original Bogen and Woodward article and the subsequent work by both of these scholars separately and in collaboration emphasized a second point about scientific practice. Whereas philosophers of science proceeding from the empiricist tradition have often highlighted the importance of observation and observations in science, Bogen and Woodward point out that many of the phenomena of scientific interest are not strictly *observable* in the sense of being perceivable by human senses. Moreover, in focusing philosophical

attention too narrowly on observations, philosophers of science have missed aspects of data collection and processing that are important for the epistemology of science.

DATA MINING

See Big Data

DATA MODELS

Data models, or *models of data*, are processed versions of data, typically prepared in such a way as to make the data usable as evidence. The term *first*

gained prominence in a 1962 paper by the philosopher of science Patrick Suppes, and after a period of relative neglect has now become an area of active research. This entry summarizes some of the key distinctions and debates, including those regarding the ontology of data, the difference between raw data and data models, the purpose(s) of data modeling, the variety of data processing methods used in the production of data models, and how data models should be evaluated.

All STEM research—indeed all empirical inquiry—is heavily reliant on data collection, processing, and interpretation; hence data models are of foundational importance. Conceptualizing the research process as involving data modeling helps to clarify the relationship between data and the world, data and theories, and the role of modeling in the scientific process.

Ontology of Data and Data Models

One of the most basic theoretical questions one can ask about data concerns what kinds of things data are. Some researchers place no restrictions on which elements of the world can count as data. On this view, laboratory mice could themselves count as data. Other researchers define data as *records* of a process of inquiry involving a physical interaction between the researcher, measuring instrument, and the world: It is only the results of observations or measurements performed on the mice colony that count as data. On this latter view, data necessarily involve a level of abstraction. Data involve replacing the thing in the world with a number, a photograph, or a recorded description. Which view one adopts arguably has epistemic implications such as whether data are unproblematically *given* or whether they are subject to the sort of questions raised by the philosophy of observation, philosophy of experiment, and philosophy of metrology (measurement).

What kind of thing is a data model? When Suppes first introduced the notion of a data model, he conceptualized them as Tarskian or set-theoretic models. Although Tarskian models are prominent in mathematics, the more commonly used notion of model in science today treats models as *representations* of some target system. Some have argued that this representational notion of a data model is

important for recognizing that data are *about* the world, and hence for making sense of their ability to serve an evidential role.

Distinguishing Raw Data, Data Models, and Models

Data models are typically contrasted with *raw data*, but it is debatable whether and how such a distinction can be meaningfully drawn. Raw data are sometimes defined to be the immediate output of an observation, measuring process, or instrument. Often, however, such immediate outputs are not yet in a form that is usable by scientists. This can occur for a wide variety of reasons: First, the data-collection process might involve some obvious errors resulting in a certain portion of *bad* data that should be excluded from the data set. Second, there could be a source of *noise* in the data signal that needs to be filtered out or subtracted. Third, the output of the instrument might be of a quantity (measurand) that is closely related, but not identical, to the data quantity of interest, and hence must be converted before being useful. Fourth, data are often discrete samples of a continuous quantity and hence need to be smoothed or interpolated. Fifth, data often need to be organized or ordered before patterns can emerge. The outcome of these various processes of data wrangling—that is, of correcting, converting, smoothing, organizing, and so on—is what we call a *data model*.

The term *data model* can refer to any type of data product, including data sets, graphs, equations, images, and even processed artifacts. Statisticians often take *data model* or *model of the data* to refer more narrowly to equations that summarize a data set or the relationships therein. On this construal, models of data are akin to phenomenological models that summarize empirical relationships without representing or positing underlying mechanisms and processes. Phenomenological models, however, are typically distinguished from models of the data by playing a broader interpretive and inferential role. Data models can also be contrasted with data-driven models, which are typically constructed through machine learning and are trained on data sets to predict the value of a dependent variable from a set of independent variables.

On the other side, data models can also be contrasted with raw data. In practice, however, this distinction too can become blurred, with the term *raw data* often taking on a relative rather than absolute meaning. There are frequently many different layers of data processing, depending on the intended use of the data, not all of which are performed at the same time or by the same researchers. Scientists thus often use the term *raw data* to describe the data model at the stage before the data processing they are about to engage in. The raw data/data model distinction also becomes blurred as measuring instruments become more sophisticated, with a lot of the data processing (correction, conversion, etc.) happening within the instrument itself. Given the substantial, and often theory-mediated, processing involved, it is not clear that even the instrument output should be called *raw*. While some researchers are comfortable with the idea that it is “data models all (or almost all) the way down,” others have tried to recover a principled distinction, such as by taking raw data to be nonrepresentational and only becoming representational when they are processed as a data model.

The Purpose(s) of Data Models

When Suppes first introduced the concept of a model of the data, he conceived of it as part of a hierarchy of models, which included not only models of data but also models of experiment and models of theory. The purpose of a data model on this view was to provide a bridge for linking theories to data. Being tied specifically to the Tarskian notion of model (which Suppes used for both models of theory and models of data), the bridge was to be effected formally in terms of the presentation or instantiation of shared structure.

Most researchers, however, see the purpose of data modeling as helping data to function better as evidence. For those who adopt a representational view of models, this involves drawing out some signal or representational component of the data to make it a more accurate or transparent representation of that feature of the world. Here the aim of data modeling is not necessarily to serve as bridge to some theory but instead to

arrive at a better or more useful data product. Some researchers argue that, rather than being part of a synchronic hierarchy to theory, data modeling should instead be viewed as part of a diachronic data lineage. Although one may use a data model to test a theory, this is just one of many possible purposes.

How Data Models Are Produced?

Many different manipulations and processes can be involved in data modeling. Some involve statistical analysis methods such as data reduction, curve fitting, correlation analysis, regression analysis, statistical significance tests or calculation of confidence intervals, and error estimation. Other data modeling methods go beyond statistical analysis but are just as essential for making data usable as scientific evidence. Which techniques should be used in a particular case will depend on the nature of the data, the aims of the researchers, and the norms of their fields of study.

All data interpretation involves theoretical or conceptual assumptions about the experimental processes by which the data were produced, which are necessary for their proper semantic interpretation. Some data-processing methods, however, can make more substantial use of theoretical knowledge in the production of data models. One widely used example is data conversion, which involves converting a measure of one experimentally accessible quantity into data about another closely related quantity of interest. Examples of this include converting data about the travel time of some acoustic or electromagnetic signal into data about depth or distance, or converting data about the height of a mercury column in a thermometer into data about temperature. Another category of data-processing methods used in the production of data models falls under the rubric of data correction, which involves removing various sources of noise from the data or correcting for other errors, such as in a process of data calibration. This may be particularly important in cases where the data have been collected in the field rather than in a controlled lab setting. A third process is data interpolation, which involves filling gaps in the data, especially when the collected data represent some continuous quantity or need to be evenly distributed in space or time for a context of

use. These are just a few examples of the many ways raw data are turned into data models, and in many cases several of these data-processing methods will be used together.

For those who think of physical objects themselves (and not just numerical or other records of those objects) as data, the production of associated data models requires methods other than statistical manipulation, such as specimen preparation (e.g., preparing fossils) or image-processing techniques for photographs. Data modeling can also involve the preparation or ordering of data for storage and dissemination, including the transfer of data from one substrate or vehicle to another (such as in transferring data from descriptive text in a book to a computer database).

There remain substantive questions about how the lines between data modeling and various other data practices, such as *data curation* or data *visualization*, should be drawn. Indeed, standardizing the definitions of these and other terms related to data processing is an ongoing project.

Evaluating Data Models

When thinking about data as the output of a measurement, data are typically evaluated in terms of accuracy, precision, and resolution. These three terms are often explicated using the intuitive analogy of a dartboard: *accuracy* is how close the dart lands to the bullseye; *precision* is how closely together a number of darts cluster (anywhere on the dartboard), and *resolution* is how thin or thick the dart point is. Precision, however, is arguably better thought of as describing the conditions of measurement, rather than the quality of resulting data. More useful is the notion of measurement *uncertainty*, which can arise from many different sources and whose estimate should accompany the data, typically in the form of metadata (i.e., data about data). The quality of data thus can also depend on the quality of the metadata that accompanies the data model. There are substantive issues in both philosophy and metrology concerning exactly how these various concepts should be defined and deployed.

In addition to the epistemic evaluation of data models, involving for example how close data values are to some *true value*, there are socially driven criteria for evaluating data models, which

are often articulated in terms of the so-called FAIR data principles. FAIR is an acronym for Findability, Accessibility, Interoperability, and Reusability. The FAIR principles are taken to apply “not only to ‘data’ in the conventional sense, but also to the algorithms, tools and workflows that led to that data” (Wilkinson et al., 2016, p. 1). These principles are central to the *open data* movement.

More generally, scholars in both the philosophy of science and metrology communities have argued that data models should be evaluated, not *in abstracto*, but rather contextually in terms of a multidimensional problem space that assesses their adequacy or fitness for particular purposes. In the *adequacy-for-purpose* view of data models, the relevant question is not just how closely the data model resembles some feature of the world, but whether or not it is an adequate data model given a certain set of resources, methodologies, and other constraints for accomplishing a particular scientific aim. This view recognizes the essential role that context plays in data evaluation; a data model of a certain accuracy, and so on, that is adequate for a scientific purpose in one context may or may not be adequate in another context.

Yet another dimension along which data models can be evaluated is ethical. Data can be collected, curated, modeled, and disseminated in ways that are biased against—and harmful to—particular communities or social groups, such as women and Black, Indigenous, or other People of Color (BIPOC). Data models can embed or obscure systematic biases, especially in social contexts such as medicine, finance, and criminal justice. For example, the Black Lives Matter movement has called attention to the ways in which racial data collected by law enforcement can be biased along many dimensions, from over-policing certain social groups to biased police reports, leading to what AI Now researchers have called *dirty data*. These data ethics issues become especially prominent when data models are used for machine learning, artificial intelligence, and other automated decision making. Such data arguably require not just an evaluation of the epistemic risks but a moral evaluation of the ethical risks as well. The Global Indigenous Data Alliance has argued that the FAIR principles of data evaluation

are inadequate in that they ignore power differentials and historical contexts. They argue for a complementary set of what they call CARE principles for data evaluation, which stands for Collective benefit, Authority to control, Responsibility, and Ethics.

DEDUCTION

Deduction is one of the two chief approaches to human thinking, the other approach being induction. Although some philosophers have proposed other approaches such as abduction, the two approaches most widely recognized by logicians remain deduction and induction. Of those two, deduction has received relatively more attention and appreciation in the history of logic and theory development and constitutes the major form of modern logic.

Deduction Defined

According to Aristotle (385–322 B.C.E.), deduction is inference from the general to the particular. Although he discussed both deduction and induction in his book the *Organon* (*The Instruments*), his primary focus was deduction, mainly in the form of his syllogism, which is still deemed as representative of deductive logic. The *Oxford English Dictionary* adopts Aristotle's definition and defines deduction as "the process of deducing or drawing a conclusion from a principle already known or assumed; spec. in logic, inference by reasoning from generals to particulars; opposed to induction."

Later logicians have broadened the definition of deduction and put more types of inferencing methods into this category. Two widely used logic textbooks, Irving Copi and colleagues' *Introduction to Logic* (14th edition) and Patrick Hurley's *A Concise Introduction to Logic* (12th edition), both define a deductive argument as one whose premises support the conclusions in the way that it is impossible (as opposed to improbable in induction) for the premises to be true and the conclusions to be false. Hurley lists five types of typical deductive arguments: arguments based on mathematics, arguments from definitions, categorical syllogism, hypothetical syllogism, and disjunctive syllogism. Arguments based on mathematical calculations, measurements, and axioms (but not statistics, which forms the basis of inductive arguments, as they infer from a sample to the population) have the validity of their conclusion fully guaranteed from the premises. An argument from a definition is deductive because the information in the conclusion is fully contained in the definition, the premise.

A syllogism is a special format of deductive argument that has two premises and a conclusion. Categorical syllogism is the classic syllogism discussed by Aristotle, in which both premises and the conclusion are either universal statements or particular statements. For instance,

Major premise: All men are mortal.

Minor premise: Socrates is a man.

Conclusion: Therefore, Socrates is mortal.

Copi and colleagues and Hurley also classify the immediate inferences such as reduction and conversion of categorical propositions as deduction and develop other type of syllogisms in the deductive system, such as hypothetical syllogism and disjunctive syllogism. A *hypothetical syllogism* adopts the syllogism format but has a conditional statement as the first premise. For instance,

Major premise: If it rains, the floor will be wet.

Minor premise: It rains,

Conclusion: Therefore, the floor must be wet.

A *disjunctive syllogism* has a disjunctive statement as the first premise. For instance,

Major premise: The flower is either red or blue.

Minor premise: The flower is not blue.

Conclusion: Therefore, the flower must be red.

Philosopher and logician Karl Popper (1902–1994), who believed that deduction is the only logical approach to reasoning, provided a clear definition of deduction. That is, a deductive statement is true if and only if when all the truth contained in the conclusion has been transmitted from the premises. He further thought that the definition is a tautology to the following one: A deductive inference is valid if and only if no counterexample exists. That statement served as the philosophical foundation of his famous theory of falsification.

Early Deduction: The Aristotelian Syllogism

Aristotle's syllogism is the most influential early format of deductive reasoning. A *categorical syllogism*, which contains three propositions (two premises and one conclusion), states a relationship between two categories, the subject and the

predicate. Those propositions fall into one of the following four types: universal affirmative proposition A, universal negative proposition E, particular affirmative proposition I, and particular negative proposition O. Aristotle called the subject in the conclusion the *minor term*, as it normally stands for a smaller category in the conclusion. The predicate of the conclusion is called the *major term*, as it normally stands for a greater category. The premise that contains the minor term is therefore called the *minor premise*, and the premise containing the major term is called the *major premise*. The term that appears in the premises but not the conclusion is called the *middle term*. All Aristotelian syllogisms can be put in a standard form, in which all statements are in the standard form of A, E, I, or O and are listed in the order of major premise, minor premise, and the conclusion. When sorted into the standard form, the validity of the conclusions can be judged by merely examining the format of the syllogism: its mood and figure. *Mood* is determined by the type (A, E, I, or O) of the propositions, and *figure* is determined by the position of the middle term. In figure 1, the middle term appears as the subject of the major premise and the predicate of the minor premise; in figure 2, the predicates of both premises; in figure 3, the subjects of both premises; and in figure 4, the predicate of the major premise and the subject of the minor premise.

In figure 1, only the mood AAA, EAE, AII, and EIO are unconditionally valid; in figure 2, EAE, AEE, EIO, or AOO; in figure 3, IAI, AII, OAO, and EIO; and in figure 4, AEE, IAI, and EIO. In the Middle Ages, a mnemonic was created to help memorize the syllogism valid in each figure, which goes:

Barbara, Celarent, Darii, Ferio que prioris;
Cesare, Camestres, Festino, Baroko secundae;
Tertia, Darapti, Disamis, Datisi, Felapton,
Bokardo, Ferison, habet; quarta in super addit
Bramantip, Camenes, Dimaris, Fesapo, Fresison

The mood of the syllogism is indicated by the vowels in the words. The mnemonic also tells how to convert all moods in figures 2, 3, and 4 into a first-figure format. If a vowel is followed by an “s,” just switch the positions of the subject and the predicate of that statement represented by the

vowel; the mood will be converted into a first-figure mood. For instance, Cesare is a second-figure mood. The “s” after the first “e” tells us that we just need to switch the positions of the subject and the predicate in the major premise to convert Cesare to a first-figure syllogism, Celarent. If a vowel is followed by a “p,” the mood can be converted into a first-figure mood by switching the positions of the subject and the predicate of the statement associated with that vowel, and the statement needs to be limited in quantity by a quantifier (converted from a universal statement to a particular statement). For example, Darapti refers to AAI in the third figure. The “p” following the second “a” shows that an AAI syllogism should be converted to the first-figure mood AII through switching the positions of the subject and the predicate of the minor premise and reducing the minor premise from a universal statement into a particular statement. An “m” following a vowel indicates the need of switching the positions of the major premise and the minor premise. For instance, the third-figure IAI (Disamis) needs to switch its major premise and minor premise (also switching the positions of the subjects and the predicates of the original major premise and the conclusion as indicated by the two “s”s) to be converted to the first-figure mood AII.

The Aristotelian syllogism must follow six rules, any violation of which commits a fallacy:

1. Avoid four terms: a syllogism can only have three terms: the major term, the minor term, and the middle term (which by definition should connect the major premise and the minor premise but not be in the conclusion).
2. The middle term should be distributed (all elements in the category described by the term are covered) at least once. An example of the middle term not being distributed at least once is: “all Frenchmen are Europeans” and “all Germans are Europeans,” from which one cannot conclude that “all Frenchmen are Germans” or any other thing.
3. If the minor term or the major term is distributed in the conclusion, it also needs to be distributed in the premise.
4. Avoid two negative premises. At least one premise must be affirmative.
5. If either premise is negative, the conclusion must be negative. If both are affirmative, the conclusion must also be affirmative.

6. At least one premise must be universal. If one premise is particular, the conclusion must also be particular. If both premises are universal, the conclusion should also be universal.

In the Aristotelian syllogism, the universal propositions imply the particular propositions with the same subjects and predicates. If A is true, I must be true. Vice versa, if E is true, O must be true. For instance, if the universal proposition “all men are mortal” is true, then the particular proposition “some men are mortal” must also be true. On the other hand, the truth of the universal negative proposition “no men are immortal” implies the truth of the particular negative proposition “some men are not immortal.” British mathematician and logician George Boole (1815–1864), however, argued that although the universal statements A and E do not imply the existence of the objects described in the subject or the predicate terms, the particular statements I and O do imply such existence, meaning “at least one object existing” in the subject or predicate terms (particular statements are also called *existential statements*). So Boolean logicians acknowledge the validity of such universal statements as “all perpetual motion machines are a good thing” or “all perpetual motion machines need no external sources of energy.” But they believe that the particular (existential) statements such as “some perpetual motion machines are a good thing” or “some perpetual motion machines need no external sources of energy” are invalid, because those existential propositions’ assumption of at least one perpetual motion machine is not met in the world.

The Aristotelian syllogism dominated the classical Greek era and the medieval era, influencing Europe significantly. According to Thomas Kuhn in his influential book *The Structure of Scientific Revolutions*, some scientists believed that if it weren’t for the domination of deductive logic, some scientific revolutions might have come earlier.

Contemporary Deduction: Logic, Math, Computer Science, and Artificial Intelligence

The greatest contribution of Boole to logic is probably his origination of the algebra of logic. A revolution to the Aristotelian syllogisms that rely on figures and moods, Boolean logic builds an

algorithm system that can be applied to an unlimited quantity of argumentations, essentially deductive, and denote the underlying structure of logic. In his book *The Mathematical Analysis of Logic* (published in 1847), Aristotelian syllogisms are algorithmized into equations to calculate the logical propositions with the help of algebraic techniques. For instance, the proposition “All X is Y” is algorithmized as “ $x = xy$ ”; “No X is Y” as $xy = 0$; “Some X is Y,” as $v = xy$ (v stands for *some*); and “Some X is not Y,” or $v = x(1 - y)$. He later developed his algebra of logic into a binary system that contains only true or false values {T, F} in his book *The Laws of Thought* (published in 1854), which laid down the foundation for deductive logic to be introduced into computer science and electronic engineering research and turns into a core part of them. His algebra of logic was inherited and developed by William Jevons, Charles Sanders Peirce, Ernst Schröder, Edward Huntington, Marshall Stone, Thoralf Skolem, and eventually Alfred Tarski, who developed a system of equations to calculate the logical relations and establish the algebra of logic within the modern logical system.

Gottlob Frege (1848–1925) established a tradition that is superficially similar to, but significantly different in nature from, the Boolean tradition of solving logic problems with algebraic techniques. Frege created a system of arithmetic notations for formal logic to fulfill Gottfried Leibniz’s idea of *universal characteristic*, a language of pure thought. When Boole’s follower in Germany, Schröder, criticized Frege for merely mimicking Boole’s work without mentioning and advancing further from it, Frege replied and argued that what Boole had created was merely Leibniz’s *calculus ratiocinator*, a system of uninterpreted markers for calculating without thinking. In his book *Begriffsschrift* (Concept-writing, published in 1879), Frege clarified that he was not creating an artificial similarity that makes concepts as a sum of characteristic marks, which he implied to be the nature of the Boolean systems. Frege’s work was actually to reduce mathematics to logic in an arithmetical form, which can help prove all mathematical problems. In Frege’s tradition, which has since been inherited by most logicians and mathematicians, mathematics is a special form of logic.

Frege’s system, however, was discovered by Bertrand Russell to have a contradiction, which later became known as *Russell’s paradox*: The

systems contains a paradoxical object: the set of all sets that are not members of themselves. To resolve the paradox, Russell introduced the notion of *logical type* and developed the theory of types, which is thoroughly discussed in the book he coauthored with Alfred North Whitehead, *Principia Mathematica*, the most popular work of logic in the 20th century. The discussion of Russell's paradox also inspired the exploration of the completeness of logic systems; namely, whether the elements of a logic system can all be deduced from its axioms. In 1931, Kurt Gödel published a paper in which he proved that no mathematical systems sufficient to embed arithmetic are deductively complete; that is, all logical or mathematical systems contain statements that can be neither proved nor disproved. Further, those systems cannot even prove the consistency of themselves. Known as *Gödel's incompleteness theorems*, those findings have caused many to suspect that a complete account of deduction is not yet achieved and probably will never be.

Frege also initiated the thread of research on predicate analysis, which, unlike traditional propositional analysis, uses concepts rather than sentences as the unit of logical analysis and therefore allows more delicate and sophisticated calculations and inferences, such as quantification analyses. The establishment of predicate logic lays down the foundation of modern logic. In Frege's predicate logic system, the most well-known symbols are the existential and universal quantifiers ($\exists x$ and $\forall y$). Frege's focus was on first-order predicate logic, in which quantifiers are applied only to variables that stand for individual objects, although he also covered second-order predicate logic, in which quantifiers are also applied to the sets of individual objects. Second-order predicate logic and even higher order predicate logic, in which multiple layers of sets of individual objects are quantified, were further developed by other logicians and eventually in *Principia Mathematica*, enabling logical analyses of arbitrarily complex situations.

The Deductive Scientific Inquiry Models

Inductive logicians have long believed that deductive logic is useful in preparing arguments but useless in scientific inquiry, because it generates no

new knowledge. On their view, induction is the only way to help people reason about phenomena outside the existing sphere of experiences and gain new knowledge.

Deductive logicians disagree, in a debate going back to ancient Greece between the Stoics and the Epicurean philosophers. Ever since the Scottish philosopher David Hume (1711–1776) pointed out the problem of induction, which reasons from the past to the future, philosophers have tried to solve the problem and develop deductive models of scientific explanation. Some philosophers, such as Popper, totally rejected induction and marked deduction as the only valid way of thinking, reasoning, and scientific inquiry. Among those deductive models, Karl Popper's falsification model, Carl Hempel's deductive-nomological (D-N) model, and the hypothetico-deductive (H-D) model are the most well-known.

Popper's Falsification Model

Popper held that it was impossible to objectively draw patterns from single facts, because all facts, when they were described, were organized on the basis of certain theories that the scientists already held. Although often perceived as a member of the logical positivism movement, Karl Popper was actually a critic of that movement, who maintained that all scientific inquiry was conducted with a system of theoretical assumptions and therefore could not start from scattered experiences and observations, as claimed by the logical positivists.

Believing that theories, or any general statements, could be logically never proved but only disproved when even one piece of counterevidence appeared, Popper argued that falsifiability was the key difference between science and pseudoscience, and that falsification was the only way to test theories. Karl Marx's theory of history, Sigmund Freud's psychoanalysis, and Alfred Adler's individual psychology were all considered as pseudoscience by Popper, because they could be used to explain any situation and no case could be used against those theories. They also could not make precise predictions. Albert Einstein's theory of relativity was classified as science by Popper, because it could develop predictions that can be tested. Such testing, however, can never prove a

real science, even if the evidence from the tests supports the scientific theory, such as in the case of the relativity theory tests. Scientific theories could only be falsified when the evidence is against them. For any real scientific theory constructed through deductive reasoning, Popper said, scientists could search for an opposite case. If the search was successful, the deduction was invalid and the theory was rejected; otherwise the hypotheses survived the falsification. Whereas inductivism scholars insist that scientific knowledge is accumulated through direct observation, Popperian deductivism scholars hold that scientists cannot generate hypotheses through direct observation, nor can they prove the hypotheses through it. Scientists can only build hypotheses through thinking and then attempt to falsify the hypotheses through direct observation. Hypotheses that can explain many phenomena and withstand multiple attempts at falsification should be deemed as good theories.

But Popper's simple falsification method could easily reject an established theory with just one demonstrable instance of counterevidence. His student and follower Imre Lakatos therefore proposed a methodology of scientific research programs (MSRPs) to improve the tolerance of the falsification method. Lakatos's MSRP classifies a theory's contents as the central theses (hard core) and the peripheral theses (auxiliary hypotheses). Disproving the auxiliary hypotheses does not refute the theory; it actually improves the theory by enhancing its predicting capabilities. A theory is only falsified when the hard core is disproved. Meanwhile, Lakatos, unlike Popper (whose subject of examination was normally a single theory), liked to think of theories as elements in a sequence that shared the same hard core. His revision to Popper's falsification method allows many useful theories to pass falsification testing. Even so, in the domain of social or natural scientific research, the falsification approach has rarely been used.

The Deductive-Nomological Model

Carl Hempel's (1905–1997) D-N model is a well-known model based on John Stuart Mill's idea that the only type of scientific explanation has the *explicandum* (explanandum), the thing to be explained, as a logical consequence of the

explicans (also called *explanans*), the thing that explains. The D-N model contains three elements: (1) A lawlike statement or theory as the premise, stating a causal relationship between factor *x* and factor *y*, such as “whenever *x* happens, *y* happens”; (2) a statement of an antecedent condition of the happening of *x*; and (3) a deductive conclusion about the consequential happening of *y*. The model is called *deductive* because it requires the explicandum to be the logical consequence of the explicans; it is called *nomological* because it requires at least one *law of nature*, a universal law that describes a class of phenomena, to be the premise. It is also referred as the *covering law model* in that sense. A simple example of the D-N model of explanation would be:

Theory (lawlike statement): Increase of the volume of media coverage on an issue makes people think of that issue as more important.

Antecedent: The volume of media coverage on education has increased.

Conclusion: People will think of education as more important.

In scientific explanation practice, the theory and the antecedent each can be a set of statements. When the theory or the lawlike statement(s) is replaced by one or more statistical statements, the D-N model becomes an inductive-statistical model, a model popular among modern inductive scientists.

Hempel's D-N model has been criticized because it assumes a universal law whose truth has been established. This type of universal law, some philosophers point out, is impossible to be found and proved. Also, no evidence can support a universal law to be true in the future, as Hume argued in his statement of the problems of induction. British philosopher Stephen Toulmin used Charles Darwin's theory of evolution as an extreme example to show that the D-N model did not explain all the theories, as there was no universal law to guide Darwin's data collection and his articulation of the theory. Toulmin and other philosophers who follow Ludwig Wittgenstein's teaching reject the idea that universal laws were the prerequisite to explain human behaviors. Thomas Kuhn also pointed out that historical studies were not based on lawlike statements. The

D-N model, marketing researcher John O'Shaughnessy maintains, also cannot explain the causal relationship that many scientists are seeking, because the D-N model provides necessary but not sufficient conditions for causal explanation. Even that necessary causal relationship is not fully established, because in the D-N model only the relationship and time order are examined, and no effort has been made to exclude the third factor. The consequential changes of x and y , therefore, can be both caused by a third party, z . Some scholars believe that the D-N model could be a great model of scientific explanation if the *why*, which addresses the underlying mechanism of causation, is included. Political scientist John Gunnell argues that although Hempel's D-N model has dominated natural science and, subsequently, social science, it is actually not an appropriate methodological paradigm for social science. He further notes that the deductive model is deficient even for natural science. According to Gunnell, Einstein, whom deductive logician Karl Popper often cited as a good example of deductive theorists, had never claimed that the relativity theory was generated through a deductive approach of thinking.

The Hypothetico-Deductive Model

The H-D model, which Popper also called *deductivism*, emerged in physics studies in the 17th century and became a major model guiding later natural and social sciences. It contains 11 steps, as summarized by O'Shaughnessy. In the first step, the scientists start to be interested in an issue and collect some perceptual experiences. In the second step, those perceptual experiences are sorted out under the guidance of existing knowledge. In the third step, when there are some difficulties to sort out those perceptual experiences into the existing knowledge system, research problems emerge. In the fourth step, to solve those problems, scientists generate speculative hypotheses. In the fifth step, a set of those related hypotheses, based on existing knowledge consistent to the hypotheses, are formulated into a tentative theory or model. Then in the sixth step, the scientists design a procedure (i.e., an experiment) to test the tentative theory. In the seventh step, data

are collected through the procedure to test the hypotheses. The eighth step, verification, shows whether or not the statistical tests in the procedure rise above the significant standard. If the hypotheses withstand the testing (the ninth step), they then are elevated as laws or formal theories in the tenth step and further become the foundation to explain other phenomena in the eleventh, and final, step.

In addition, O'Shaughnessy divides the H-D model into six stages: domain image, problem identification, speculative hypothesis, tentative model, prepare for testing, and testing.

1. *Domain image.* In each field, a system of presuppositions exists to define the boundary of the academic domain. Actually, even scholars in the same domain may have different biases in their theoretical or methodological backgrounds. Those domain images or researchers' own backgrounds may not be right, but they are the fundamentals on which those researchers construct their theories.

2. *Problem identification.* All research projects start with goals of solving certain problems. Those problems are inconsistencies or puzzles that the researchers have identified in the conceptual system of their domains. Although solutions to those questions can be from all domains, researchers tend to find the solutions from their own fields, owing to their theoretical and methodological bias.

3. *Hypothesis.* The speculative solutions to the problems that researchers come up with are hypotheses. Hypotheses to scientists, as Popper stated in his autobiography *Unended Quest*, are like nets to fishermen. Scientists who do not use hypotheses cannot capture knowledge. With the increasing emphasis on the function of hypotheses, social scientists have also been studying how to effectively generate hypotheses. Social psychologist William McGuire, for instance, recommended about 100 techniques to help researchers generate hypotheses, although most of the methods are inductive in nature.

4. *Tentative model.* When the hypotheses are connected with each other and with existing concepts and propositions in the knowledge system

in that domain, a tentative model is formulated. Tentative models are postulated, rather than evolved from induction. Based on that statement, H-D scholars also believe that science is more like being invented rather than being discovered. It is essentially a perceptual reconstruction of the object. It describes the relationships among the concepts related to the problem under study. When the underlying mechanism of the relationships is included in the model to explain why those relationships exist, the model is further called a *theory*, a term that contains more substance in the philosophy of science.

5. *Preparing to test.* Preparation for testing is basically a process of connecting the theoretical concepts to the observable world through conceptual analysis. The first step of conceptual analysis, as communication scholar Steven Chaffee points out, is meaning analysis, through which a concept's intention (connotation) and extension (denotation) are articulated. Based on meaning analysis, definitions should be provided. Although analytical definitions, which state the relationships of concepts to their superordinate concepts, have been the traditional format of definition, operational definitions are instrumentally more important format of definition that theorists need. Operational definitions connect the concepts to observable indicators that scientists can measure with human senses, with or without the help of research devices. The research on how to develop operational definitions for theoretical concepts, also called *constructs* in some textbooks, is known as *measurement*. Operational definitions must be constructed based on thorough understanding of the analytical definitions. Certain concepts need no operational definition, because they are not abstract or far away from people's senses, such as people's demographical factors, or because those concepts are created based on empirical measures, such as economic indices.

6. *Testing hypotheses.* Traditionally, scientists test a hypothesis by first deducing an observable logical consequence from it and then testing the logical consequence. If the consequence is tested and observed, the likelihood of the hypothesis being true is raised. If the confirmation fails, the

hypothesis is not supported, but need not necessarily to be abandoned.

The influence of the H-D model can be seen from a model of scientific inquiry in a book written by education researcher Frank Kerlinger, *Foundations of Behavioral Research*. Kerlinger, on the basis of John Dewey's analysis of reflective thinking, proposes a four-step scientific approach, which has become influential among not only education researchers but also researchers in many other social science fields, such as communication, marketing, and psychology. In the first step, problem-obstacle-idea, scientists experience some difficulties in explaining certain things and formulate a statement of the problem. In the second step, based on past and/or present experiences, the scientists turn the problem into a hypothesis, a conjectural or tentative proposition. In the third step, the scientists conduct reasoning-deductions. This, according to Kerlinger, is the most important yet often overlooked step. In order to further test the hypothesis, the scientists need first to deduce testable consequences from the hypothesis. In the fourth step, the scientists find ways to test the consequences deduced from the hypothesis. The process is not necessarily always in that chronological order, and latter steps may happen before the previous steps have been completed. Preconceived ideas (problems or hypotheses) are the guides for collecting relevant facts, testing the hypotheses, and accumulating knowledge. Kerlinger highly values the role of hypothesis in his model. Hypotheses, he wrote, are working instruments of theory, without which no science would be possible, because hypotheses can be tested and shown as correct or incorrect apart from their creators' opinion or evaluation. Whether or not the hypotheses are confirmed, knowledge is advanced. The Kerlinger model of scientific inquiry is essentially a miniature of the H-D model.

Despite its domination in academia even today, deductive models of theory development, in particular the H-D model, cannot explain all the significant discoveries in many fields. In addition to Toulmin's citing the evolution theory as a counterexample, O'Shaughnessy also cites voyages of discovery as a good counterexample of the

deductive model of scientific exploration. An instance of scientific inquiry that arrives at a wrong conclusion is not totally useless. Voyagers often fail to find what they seek, while finding other things of great value and interest.

DEVELOPMENTAL SYSTEMS THEORY

Developmental systems theory (DST) is a comprehensive theoretical framework on biological development, heredity, and evolution. A metatheory about complex systems in nature, DST spans the fields of philosophy, biology, and psychology, providing a structure for the study of interactions among multiple factors that drive development. It offers a thorough understanding of human development by combining explanatory forces of nature and nurture, genes and environment, and biology and culture. This entry explores the history of DST, its definitions and characteristics, key concepts and themes, and future directions.

History of DST

DST is a general theoretical perspective based on the rich history of work by scholars in the implementation and interpretation of developmental science. Unlike many other theories, DST is not an individual theory offering predictions for empirical testing and based on the work of one person. Rather, on the basis of discussions and research by numerous philosophers and biologists of the 19th and the 20th centuries, psychologists in the 1970s began to develop a systems approach to human development, grounded in developmental and behavioral psychology, which has attracted the interest of, among others, molecular biologists and philosophers of biology.

Philosophers and scientists have been interested in development of humans and other organisms since ancient times. As a result of the progress in anatomical studies in the 17th century, two chief viewpoints emerged. *Preformationists* asserted that the development of the organism was simply an unfolding of inherited structures. *Epigeneticists*, however, thought that the organism became more complex during development, in which physical structures develop from indistinct germinal material. By the 19th century, the continuing improvement of early microscopes enabled the analysis of egg cytoplasm and discussion of the processes of differentiation and maturation. Similar to the debates between nativists and empiricists in philosophy, these two camps also focused on innate complexity versus gradual development. These parallel discussions paved the way for the emergence of psychology and evolutionary biology.

In the late 19th century, instincts started to be studied in humans owing to the influence of Darwinian evolution on psychology. In studies of comparative psychology, nonhuman animals were experimentally tested in laboratories for their learning behavior in isolation from their instincts as observed in natural settings. Functionalist psychology in the early 20th century in the United States made extensive efforts to understand the role of instincts in human behavior. Psychologists such as John B. Watson (1879–1958) and his followers then turned away from instinct because of its innate and indefinite

nature. Behaviorism, according to Watson, was the science of observable behavior. Behaviorists' emphasis on learning and experience and devaluation of innate and heredity factors turned psychology into a nondevelopmentally oriented discipline.

Early studies of child development by G. Stanley Hall (1846–1924) and Arnold Gesell (1880–1961) were initially not accepted into mainstream American psychology because of their methodological and theoretical perspective. In Europe, ethological studies on animal learning and development, especially by Konrad Lorenz (1903–1989), turned the focus on instincts again. Instincts were essential for animal behavior and independent from, and in some ways superior to, learning experiences. Phylogenetic information providing a base for all innate behavior offered a genetic blueprint for development, whereas environment played a largely supportive role. Criticisms of Lorenz's work by the naturalist and animal psychologist Daniel S. Lehrman (1919–1972) rejected the dichotomy of innate instincts and learned experiences. Lehrman's integrationist perspective is accepted as one of the first discussions of DST.

The discovery of the structure and function of deoxyribonucleic acid (DNA) in the early 1950s and later studies shed light on the molecular-level processes of inheritance, development, and behavior. Subsequently, the notion of genes as the chief or sole determinant of behavior was replaced with a two-way perspective that recognized the role of the environment, experience, and learning as well as heredity. According to Gilbert Gottlieb's model of probabilistic epigenesis, proposed in 1991, genes identify the neural structure, which influences and is influenced by the physiological function, which also has a reciprocal relationship with behavior. In their 1992 book, *Developmental Systems Theory: An Integrative Approach*, Donald H. Ford and Richard M. Lerner first presented the DST. Building on a rich history of scholarly work, they emphasized contextualism and dynamic interactionism in the process of development. Since then, most research grounded in the DST perspective has focused on human behavioral development, while DST-based philosophical discussions have contributed to the

theoretical discourse of molecular and developmental biology.

Definitions and Characteristics

Richard M. Lerner has outlined the defining features of developmental systems theories. According to Lerner, DSTs are relational metamodels that bridge many dichotomies such as nature–nurture, genes–environment, continuity–discontinuity, stability–instability, and biology–culture. All levels of organization within developmental ecology, from biology and psychology to culture and history, are integrated. Development is regulated by mutually influential connections between all levels of the system such as family and community, or individual and social context. The basic unit of analysis in human development consists of integrated actions between person and environment. The temporality and plasticity of human development allows different trajectories of intraindividual change. Plasticity of development is relative across the life span, the history of the individual, and the social/environmental context. Different levels and variables produce diversity and change between and within individuals, which is fundamentally significant for the study of human development. Applications of developmental science through interventions and policies can promote positive human growth. The integrated and multilayered nature of developmental systems requires scholars and researchers to exercise multidisciplinary knowledge and methodologies sensitive to change at all levels.

Within its multidisciplinary framework, DST is subject to certain inaccurate representations. First, DST is not just a philosophical perspective on biology but is based on, and in turn influences, experimental and empirical studies of development. Although DST is sometimes believed to emphasize only the developmental aspect of evolution at the expense of natural selection, in fact DST emphasizes the generative aspect of evolutionary development as well as its selective and adaptive nature. Some others have assumed that DST downplays the role of genes in development. On the contrary, DST recognizes the effects of genes as well as nongenetic factors on development and includes both factors in developmental

systems. The DST perspective posits that the genes do not simply code or specify behavior but, rather, influence the way a particular behavior develops. Roles that genes play in development are neither minor nor simple, but they are not in competition with nongenetic factors; rather, genes are in coevolution with them.

DST is also different from many other fields of development such as quantitative behavioral genetics and nativist cognitive developmental psychology. It even developed as a response to the formulations and methods of these fields. Behavioral genetics tried to account for the relative contributions of genes and environment to individual differences. DST objected to the focus on relative weights of factors and to the supposed duality of nature and nurture. Instead, it aimed at a process explanation of developmental mechanisms and their dynamic interactions. Nativist cognitive developmental psychology, exemplified by Noam Chomsky's linguistic acquisition device, posits innate faculties in several neurocognitive domains that shape children's cognitive development. DST also criticizes the nativist approach for its predetermined maturational view on development that minimizes the power of environmental forces.

Key Concepts and Themes

In the context of DST, epigenesis and developmental dynamics stand out as two core concepts. In contrast to preformationism and predeterminism, epigenesis puts forward that development unfolds by leading to increased complexity. It is not simply formed or determined in advance by biological structures or environmental factors. Similarly, epigenetics focuses on mechanisms and processes of genotype leading to a certain phenotype. *Epigenotype* includes multiple genes in the expression of a phenotype. DST enriches epigenotype by including nongenetic factors among the causal factors of the developmental process. Owing to the probabilistic nature and plasticity of development, a certain phenotype cannot be caused or determined by the mere addition of these factors. Rather, development is a contextual, interactive, and dynamic process.

The concept of developmental dynamics implies that the developing organism is in constant

dynamic interaction with its environment during which both the organism and the environment change. There are bidirectional influences between genetic and neural systems as well as between the behavior and the environment of the organism. Similar to the complex system of biological structures, environment is composed not only of physical but also social and cultural environment. For an accurate representation of development, these dynamic interactions between multiple layers should be studied over time in the course of development.

In their seminal work, Susan Oyama, Paul E. Griffiths, and Russell D. Gray outlined six key themes of DST as (1) joint determination by multiple causes, (2) context sensitivity and contingency, (3) extended inheritance, (4) development as construction, (5) distributed control, and (6) evolution as construction. According to the first theme, development is shaped by multiple factors that work together in an interactive fashion rather than an additive style. As for the second, development takes place in a multilayer context, and the context determines which factors will dominate others during this process. Third, the development and life cycle of the organism is driven by a broad range of inherited genetic resources. In the fourth theme, development is a constructive process that is not solely determined by preexisting inherited traits but constructed by the developing organism throughout the process. The fifth theme implies that development is not controlled by one type of factor alone but shaped by a fluid and diffuse set of factors. In the sixth theme, development includes evolution of the organism–environment systems rather than the evolution only of individuals or populations.

DST explains development through dynamic and mechanistic explanations: mechanistic because they present arrangements of factors within developmental systems, which lead to those processes; dynamic because processes result not only from the arrangements of factors but also from the dynamic operation of the mechanism. Bidirectional influences between factors from different levels work via top-down or bottom-up causal mechanisms. Such factors do not operate in isolation but work in a context of a whole set of other variables. In truly developmental explanations, the aim is not to explain causes of individual

differences but to explain developmental systems' potential to lead to these differences and other consequences.

Future Directions

Recent writings on DST have tried to offer integrationist views together with other perspectives such as evolutionary developmental biology (EDB) and evolutionary psychology as well as the Advaita philosophy of nonduality. Different interpretations of inheritance and an emphasis on genes led to a mutual exclusion between DST and EDB. A systematic and cross-disciplinary research program may help to close the gap between the two. Both DST and evolutionary psychology make use of self-organized patterns of development from genes to culture as well as probabilistic mechanisms of development in ontogeny (life span development) and phylogeny (across generations). A dynamic optimization method has been found to be useful for the integration of the two fields. Advaita philosophy, originating in the Vedanta tradition of India, and similar to the nondualistic aspect of DST, proposes a holistic and interconnected view of individual and cosmos.

In addition to the theoretical expansions, there have been conceptual and methodological advances offering clues about the future directions of DST. Integration of key concepts such as probabilistic epigenesis, dynamic interaction, and self-organization has led to a relational DST. The relationist view provides a richer understanding of development with embodied actions of a holistically organized developmental system. The relational biopsychosocial model synthesizes person, biology, and the sociocultural, whereby each component develops through co-construction and coevolution. Furthermore, the introduction of simulation models and dynamic modeling techniques has opened new fronts to DST. Connections and directionality among variables at inter- and intraindividual levels are better represented through these methods. Advanced analytical tools provide better means of studying the nonlinear, self-organizing, and complex nature of development.

ENGINEERING, CONTEMPORARY

While engineering includes a subdiscipline called *engineering science* (statics, dynamics, thermodynamics, etc.), engineering, even engineering science, is not a science strictly speaking, not even a practical science. No part of engineering—design, testing, operations, maintenance, documentation, disposal, or the like—seeks to understand any part of the world as such (as science typically does). Instead, engineering attempts to change the world. Understanding (when it occurs in engineering) is a mere byproduct of that attempt. The primary vocabulary of engineering consists of directions: designs, specifications, maintenance schedules, and so on. The search for ways to change the world is what makes engineering a technology—like architecture, accounting, public health, and so on. What makes engineering, including engineering

science, different from most, perhaps all, other technologies is that engineering attempts to improve humanity's material condition without any upper limit to the improvement. Other disciplines recognize an upper limit after which there is nothing more to do, for example, the public welfare (the upper limit of public administration) or health (the upper limit of medicine).

Engineering's emphasis on unlimited improvement makes *theory* in engineering different in important ways from theory in a science (strictly speaking). For the sciences, theory is an aid to understanding; for engineering, theory is a guide to action, not simply in research (as in science strictly speaking) but also in invention, manufacture, quality control, construction, maintenance, and disposal in the world. For engineers, understanding is itself only a possible means of improving the material condition of humanity. Consider, for example, how differently research into metal fractures might be conducted in science and in engineering. Scientists (typically, physicists) will want to develop a theory that identifies the forces contributing to a fracture, explain fracture in terms of those forces, and perhaps use that explanation to predict fractures. They will not be concerned with design, that is, with means of reducing fractures in a mixed material in ordinary use (such as the alloys in the wing of an airplane). Engineers will.

Theory in General

Whatever else it is, a theory is like a seat in a theater. It offers a particular perspective on the world understood according to a certain discipline.

A discipline consists of a limited vocabulary in which to express claims, *prima facie* modes of proof, or other formalized ways of acting. For example, physics tries to understand the world (*the physical world*) in terms of waves, mass, time, space, and other physical properties expressed mathematically and tested by observation, prediction, deduction, and experiment. Though physics has something to say about every particle in the universe, however large or small, it is not a *theory of everything*. It is, for example, silent about how to arrange the world to increase accessibility, safety, or comfort. Neither *accessibility*, *safety*, nor *comfort* is in its vocabulary. Those three terms belong to other disciplines, such as interior design or public health.

Engineering theory typically differs from theory in the sciences in focusing on usefulness rather than on understanding. Engineering theory typically differs from theory in other technologies in having as its purpose improving the material condition of humanity. Most technological disciplines serving the material condition of humanity (architecture, public health, interior design, etc.) attempt to be useful but not (like engineering) *progressive* (contribute to human progress). For example, architecture is typically defined as an occupation concerned with designing and overseeing the construction of buildings to meet the requirements of building codes, the contract with the client, and generally accepted aesthetic standards. There is no requirement that tomorrow's architecture be better than today's.

If technology consists of a set of relatively reliable procedures for managing some aspect of the world, then a flight of fancy cannot be technology. Indeed, it must be *pseudo-technology* insofar as what it uses is necessary to claim that reliance. For example, an invention cannot be useful if its usefulness would violate the third law of thermodynamics (entropy). That law is too fundamental to technology for one invention to overcome the evidence supporting it gathered over several hundred years.

Although engineering is generally as hostile to pseudoscience as science itself is, it is not always hostile in the same way. For example, engineering may treat as fact claims for the safety of a design standard when the only support those claims have is *engineering judgment* (engineering's equivalent of common sense). Some of the standards in building codes, the highway's "Green Book," and the like

have no other support. Engineering judgment is a standard of proof more rigorous than common sense but less rigorous than what science or technology typically requires. Generally, engineers appeal to engineering judgment when no one is willing to pay to do the research necessary to confirm or disconfirm the hypothesis or the necessary research would be unethical or the research is otherwise impractical, and the projects require a common standard more rigorous than common sense. Engineers do not use engineering judgment to support a theory just because they regard engineering judgment as sacrosanct or even particularly reliable. Engineering judgment is merely better evidence than nothing (common sense or a flight of fancy).

A hypothesis receives confirmation when research, done according to the appropriate discipline, uncovers evidence in its favor (i.e., facts encouraging reasonable trust in the hypothesis); it receives disconfirmation from the uncovering of disfavorable evidence. The discipline determines what counts as evidence for or against.

The distinction between *pure science* and *practical science* is hard to state briefly in a way helpful for understanding the role of theory in engineering. Most sciences seem to have both a pure side and a practical side. The pure side seeks understanding of the world for its own sake, for example, knowledge of how to construct a chemical compound with certain elements arranged in a certain way. The pure theorist is unconcerned with how that understanding will be used outside their office, laboratory, conferences, and journals. In contrast, the practical scientist seeks understanding for the sake of something *in the world*, for example, a new explosive for lunar mining. Whether any scientist is *absolutely pure* or *absolutely practical* is a question for empirical research. The same may also be true for some technologists, such as architects or computer scientists, but not for engineers. There does not seem to be a use for a distinction between *pure engineering* and *practical engineering*. Engineering (and engineers) are practical by definition, and so are engineering theories.

At least since about 1800, engineers have defined engineering as aiming at the improvement of humanity's material condition. "Humanity's material condition" connects engineering theory with physics, chemistry, and other material sciences, while *improvement* connects engineering

not only with economics, psychology, and other human sciences but also with practical reason (prudence, morality, and ethics). No activity can be engineering if it only seeks understanding for its own sake.

Engineering Theory and Technology

Though the exact meaning of the term *theory* seems to vary with the discipline studied, in general, theory is distinct from fact. So, for example, when lawyers talk about *the theory of a case*, they mean the story used to arrange the facts of a case into a reasonable or persuasive order, including *facts* still to be established. For lawyers, the facts are what they think they can prove in court. A good theory of the case is a way to present the facts likely to win a favorable judgment. Unlike theory in the sciences, the lawyer's use of *theory* in *theory of a case* has no (necessary) connection with truth. (Lawyers are rhetoricians, not scientists.)

Like most important terms, *technology* also has several meanings. In one, technology means the sum of processes, skills, and machinery used in the production of material goods (anything from books to bombs). The sum of processes, sources of power, skills, and machinery used in the production of immaterial goods, such as poetry or a social event, is not, as such, technology. So, for example, someone might properly say of the gradual shift from watches (time pieces) with mechanical innards to watches with electronic innards that "digital technology is replacing mechanical technology." However, one cannot (in this sense) properly say of the Protestant Reformation's switch from the Latin liturgy of the Catholics to a vernacular liturgy of the Protestants that "during the 1500s the technology of Protestantism replaced the technology of Catholicism in the sects of the Reformation." Being largely immaterial, the religious practices in question are not technology. It is better to speak of them as "the culture of Protestantism" and "the culture of Catholicism."

In another sense, however, *technology* refers to any system by which humans and machines work together to accomplish some practical end, whether material or not. This sense of *technology* includes culture insofar as, for example, religion relies on machines for its special foods, building designs, procedures for circumcision, ways to remember prayers, and so on.

In yet another sense, *technology* refers to systematic investigation or knowledge of technology in one of the other common senses of that word—as in such terms as *institute of technology*. Technology (in this sense) is the study of technology (techne or techniques) in one or more of the following senses of *study*: (1) passing knowledge (including knowing-that, knowing-how, knowing-when, and knowing-why) from those who have the relevant knowledge to those who do not (training or education), (2) the discovery of new knowledge of the relevant sort (research), and (3) the invention of new artifacts or new ways of producing artifacts (design).

While much technology (in one or another of these three senses) relies on scientific knowledge (natural or social), much does not. For example, the dyeing of fabric was industrialized long before the chemistry of dyeing became a science. During that prescientific age, knowledge of dyeing was largely the secret of this or that trade. That is one reason to think that technology is not just applied science.

That, of course, is an historical reason. It leaves open the question whether all technology might be applied science in the more radical sense that all technological knowledge is logically reducible to one or more of the sciences—in principle if not in practice. The answer to that question seems to depend in part on what counts as science as well as what counts as technology and reducibility. If *science* means natural science (the disciplined understanding of nature), then there is good reason to reject the claim that this or that technology relies (or must rely) entirely on one or more of the sciences. Science, in this sense, is an attempt to understand the natural world in a certain way (according to one or more scientific disciplines); but technology is, at a minimum, an attempt to change the world in a certain way. Even a true and complete understanding of nature cannot provide instructions, guidelines, or the like for changing the world—in however small a way.

There are, of course, less strict ways to understand *science* that include systematic understanding, explanation, or knowledge of nonnatural fields (artifacts or processes) as well as of natural ones. A field is nonnatural insofar as its facts depend in part on what ordinary humans do (or think) rather than on what researchers do (or think). Thus, the human sciences (history, psychology,

sociology, etc.) must be at least in part nonnatural because, for example, history is in part about what people thought—their purposes, motives, and so on. The nonnatural sciences must be *practical* insofar as they include systematic understanding of how to accomplish certain practical ends. Is this systematic understanding the link between the contemplation of science and the activity of technology?

Among the nonnatural sciences are *computer science*, *medical science*, and *political science*. Computer science is both about mathematics (or symbolic logic) and business practices (such as the processing of job applications or census data); medical science, both about how the human body reacts to various diseases and about which medications may be prescribed for which disease; and political science, both about how government works and about what politicians may do to stay in office. But even if *science* is stretched to include the study of such practical sciences (in any or all of the three senses of *study* identified earlier), technology is still not merely the application of the sciences to the world's practical affairs, such as ordering replacement parts for a stamping press or deciding that the wing on an airplane is flexible enough for ordinary use. Science, even applied or practical science, only identifies ways the world may be changed. No science recommends a way the world should be changed. The scientist who wants to order replacement parts or say that an airplane wing is safe enough for flight must go beyond the sciences and act as a technologist.

Engineers and the Philosophy of Technology

For our purposes, the philosophy of technology is the attempt to understand the reasonableness of technology. The reasonableness of a fact, activity, or practice depends (in part at least) on its definition. Definition can be difficult. For example, the philosophy of technology has long debated which *values*, if any, *technology* includes or should include in its definition.

The traditional view seems to have been that technology is a *pure means* for rational agents (persons who are prudent but not necessarily moral). Thus, the slogan “Guns don’t kill people; people kill people” treats guns as a pure means.

The source of the bad effect of guns is the people who use them—both rational agents and those suffering from one or another mental disability. If guns were not available, people would find other means to kill—a kitchen knife, a cast iron frying pan, a rock. Guns have no agency of their own.

A more recent view is that *intrinsic values* are (or can be) designed into a technology whether the designers know it or not. This treats artifacts, such as guns, as having an agency of their own. On this view, the proper response to the slogan “Guns don’t kill people; people kill people” is “People seldom kill people on their own; more often, guns make the killing easier. Take away the guns and there will be less killing.” The guns in question are in the causal chain just as much as people are (when a gun is used).

Another recent view rejects *rational agents* as the typical participants in technology, substituting *the reasonable person*. Reasonable persons are, of course, prudent (most of the time at least) and have a basic knowledge of the world. They can plan. Their plans typically suit their desires. And their acts typically suit their plans. In these respects, reasonable persons are much like rational agents. The most important difference is that reasonable persons typically care about others while rational agents do not (especially the rational agents of economics). Another important difference is that reasonable persons recognize morality as a desirable constraint on everyone’s conduct, not as a mere cost of doing business, as rational agents do. These two differences are empirical (as well as theoretical). There is considerable evidence that most people do in fact care about others, not only family and friends but also people more distant, such as victims of oppression in other countries, though distance does seem to reduce the strength of their caring. Most people probably care most about themselves and their immediate family, but people who care only about themselves (the merely prudent) seem to suffer from a character flaw. Among the reasons for people to care about morality is that they care about others, including children and the disabled, and morality protects such people.

Engineers seem to design for reasonable persons who are not always at their most reasonable. They try to foresee distraction, exhaustion, ignorance, and the like and seek to prevent such disabling factors from causing *operator error*. Indeed, engineers

typically try to make the artifacts or processes they design *foolproof*—or at least as foolproof as budget, organizational policy, regulation, and the like allow. Other technologists seem to work to a different standard, for example, protecting the reasonable person (but not the fool) from suffering or causing serious harm. Moral theory, rational decision theory, and human factors analysis have an important place in setting design criteria and in evaluating them after the design has entered the world as an artifact or process.

There is, at any time, a practical upper limit even to engineering's *safety factors*. Typically, that limit is set by the market. If unit cost of an artifact or process (after including the cost of design, production, operation, maintenance, disposal, and reasonable return on investment) exceeds what people are willing to pay (*demand*), there will generally be no market for that artifact or process. The exception will be for those artifacts (or processes) that have subsidy lowering the market price enough to be attractive. The most common subsidies come from taxation (to support parks, roads, public schools, and other government services) and grants from private charities (supporting libraries, museums, hospitals, and other nongovernmental agencies). Such exceptions from market control are typically defended as correcting for *market failure* (e.g., for the fact that everyone benefits more from the practice of sharing roads built at public expense than they would from the practice of letting each landowner build his own stretch of road and take tolls from users).

Most new artifacts (or processes) that engineers design replace similar artifacts. The new artifact should be better than the old (i.e., improve humanity's material condition). Among the factors making an artifact better than what it replaces is lower cost (because of use of cheaper but equally reliable materials, use of less material, or a better manufacturing process), other improvements in *technology* (such as more functions, lower weight, and easier disposal), and better support (design making repair or recycling easier). If the cost of an improvement in design is, all else equal, negligible, an engineer should automatically include the improvement in the design to raise the *state of the art*. If the cost of the improvement is significant, engineers should propose it to the organization

for which they work. When, however, substantial improvement competes with substantial cost, engineers can rarely decide the question by appeal to economic theory or engineering judgment. Determining whether the improvement should be made seems to require a social decision—or at least a decision involving more than engineers consider (or should consider) to be within their competence. The question of when a decision is best left to an expert and when it is so political that the public should have a part has been a lively subject in political theory since the ancient Greek philosopher Socrates.

When engineers speak of *a design*, they typically mean the documents giving instructions for carrying out some major undertaking, say, the building of a new cracking tower or manufacture of a new microchip. This is design with a *big D*. Less often, engineers use *design* to mean the instructions for carrying out smaller projects, such as a proposal for replacing lead pipe with copper in the water delivery system of a 12-floor apartment building. Most designs, even small-d designs, typically rely on engineering theory of one sort or another.

Theory in Engineering

Though the term *theory* has many senses, those senses generally have this much in common: there is a *story* (a set of hypotheses) on which to hang facts, especially new facts that experiment, observation, or reasoning reveals or might reveal. The understanding that a scientific theory promises consists not primarily in the new facts it leads to but in the proposed *story* that the facts, old and new, make increasingly plausible, increasingly coherent, and increasingly suggestive of new hypotheses. Much the same is true of engineering theory—except that its research typically identifies directives that ought to be followed (or not), for example, the *fact* that *Y* is best for some purpose.

Theories may, then, be thought of as guides to research (suggestions possibly leading to interesting hypotheses or whole research agendas or as organizers of (supposed) facts (facts that support one or more hypotheses). Most theories belong in both categories. Calling a certain set of hypotheses *a theory* usually signals a research agenda, one that may, when followed, confirm or disconfirm

the theory. But once a theory has been confirmed enough to become central to an important science or technology, it *dies and goes to heaven*, that is, it ceases to generate interesting research concerned with its confirmation or disconfirmation and instead contributes to science and technology in less direct ways, especially by offering a useful perspective on a family of research agendas.

Insofar as that is true, *engineering theory* has a weaker analogy with theater than *scientific theory* does. In a theater, the audience (typically) observes the actors. It does not interfere with them. The actors are *nature*, that is, that part of the world that the science in question crafts its theories to understand. In engineering, however, theory is (in part at least) about how to interfere with the actors (typically the human beings and natural processes affecting human artifacts or processes) to achieve some material improvement in human life. For example, engineering can reduce the risk of accident by designing an appropriate schedule for inspecting an airplane's wing for signs of fracture. Designing the appropriate schedule will, of course, require engineers to consider at least two factors foreign to natural science: cost and safety. An appropriate schedule will not waste resources by, say, starting inspections of the wing too soon or by using uninformative tests. An engineer's schedule will, however, typically include a *safety factor*, that is, enough redundancy in the required inspections to allow for the effect of unusual temperatures on test devices, the occasional exhaustion of inspectors, and so on.

Because controlling cost and assuring a large enough safety factor are competing considerations, even designing a simple inspection schedule for an airplane's wing may require a complex theory, one directing how to determine and weigh moral considerations such as waste and safety, as well as facts about the nonhuman world, such as metal fatigue. Neither the natural nor social sciences will have much to contribute to the relevant theory. It is engineering.

ENGINEERING, HISTORY OF

The history of engineering represents essential knowledge for today's engineers, showing how engineering ideas, training, and practices evolved in different countries and cultural contexts. Multiple intellectual, social, and political factors shaped centuries of engineering, including the formalization of education, professionalization of expertise, corporate and government connections, wartime demands, and pressures of economic competition. Recent decades have highlighted ongoing issues, including engineering and ethical responsibility, modernization and training accreditation, and strategies for diversifying engineering perspectives by widening access to women and others historically underrepresented.

Early History of Engineering

Engineers existed even before that term came into use, practitioners who developed practical tools, buildings, and infrastructure. Across early Africa, the Mediterranean, Asia, and elsewhere, innovators (names lost to time) created and improved agricultural implements, food storage systems, early textile-making and metalworking, new boat forms, and navigation techniques. Creators planned and managed construction of Stonehenge and other prehistoric monuments, Egypt's pyramids, Greek and Mayan temples, and defensive walls in cities across cultures. Skilled leaders supervised the movement of thousands of tons of material (without modern mechanization) to create massive stonework, often with precise angles or aligned with the stars. Planners designed and managed construction and maintenance of Inca road networks, early Middle Eastern and Chinese canals for irrigation and transport, and Roman systems of roads, sewers, and aqueducts, all stretching across hundreds of miles.

Similarly in medieval Europe, master masons and other men, with no formal engineering degrees but years of hands-on experience, directed design and erection of soaring Gothic cathedrals. Well-designed waterwheels powered manufacture of cloth, flour, iron, and other goods, driving increased commerce and economic growth. In China, specialists refined and expanded production of iron,

steel, and bronze, metallurgical knowledge applied to make more efficient plows and other farm tools, stronger weapons, and ceremonial objects such as bells. Other innovators in China created faster ships and magnetic compasses for long-distance exploration and trade, plus early kites and gliders, silk-manufacturing tools, and fireworks, including gunpowder rockets and projectile weapons. In the Islamic world, Ismail al-Jazari created and described numerous the so-called *ingenious devices*, including clocks and automata for amusement.

European Military Engineering

The word *engineer* originated around the 1300s, commonly referring to men who specialized in devising military constructions and derived from Latin words meaning "to create or invent." Warfare in early modern Europe offered engineers employment in designing new weapons and fortifications for wealthy patrons. Leonardo da Vinci (1452–1519) spent years inventing improved catapults, cannons, and muskets for Italian and French rulers, while also designing canals, bridges, industrial machines, cathedrals, and fortifications. Leonardo's impractical but bold ideas for armored tanks, attack submarines, and flying machines made his name synonymous with brilliant creativity. But Leonardo built on the work of earlier engineers, including Germany's Konrad Kyeser (1366–c. 1405) and Italy's Mariano di Jacopo, known as *Taccola* (1382–c. 1453), who wrote books conveying specialized knowledge of the era's arms-making and other machinery. Italy's Francesco di Giorgio Martini (1439–1501) revolutionized the design of military fortifications for the age of artillery. Like Leonardo, he combined work in engineering and art; both men applied metalworking expertise to make military cannons and also decorative statues. Italy's Vannoccio Biringuccio (1480–1539) and Germany's Georgius Agricola (1494–1555) published masterworks on mining engineering and metallurgy. Agostino Ramelli (1531–c. 1610) served as a military engineering consultant in both Italy and France and published many machine designs, especially hydraulic devices for raising water. Dutch engineers such as Cornelius Vermuyden (1595–1677) specialized in swamp drainage and water management for land reclamation.

Europe's link between engineering and state military priorities continued through the 1600s, highlighted by the fortification and siege machine designs of France's Sebastien de Vauban (1633–1707). By the 1770s, French leaders had established the École Nationale des Ponts et Chaussées, an institution to foster new generations of experts in road and bridge engineering. Educators wrote the textbooks for their new curriculum, focused on mathematical theories of structures and scientific understanding of materials. In the late 1700s and early 1800s, France opened several new institutions to teach engineering, machinery, and mining, including the famous École Polytechnique of 1792. Graduates primarily served in France's military, linking technical command to state power, but others took positions in French industry and urban planning. French engineering theory fostered key developments in thermodynamics, hydrodynamics, vibration, and statics. Due to the era's links between technical knowledge and military needs, the military academy at West Point became the first school in the United States to teach engineering, feeding into the U.S. Army Corps of Engineers. Graduates also led in creating roadways, bridges, canals, and harbors for a rapidly growing nation.

Industrial Revolution Engineering

Well into the 1800s, many men continued to fulfill engineering duties without academic qualifications. Britain's Industrial Revolution relied on experts trained through apprenticeship, focusing on practical knowledge. British textile mills, other factories, and iron-making blast furnaces needed dependable power sources. Thomas Newcomen (1664–1729) transformed earlier steam devices to create an atmospheric engine useful for pumping water out of deep mines. Instrument maker James Watt (1736–1819) then improved Newcomen's design by adding double-acting mechanisms and a separate condenser. His more efficient and versatile steam engine promoted expansion of large-scale manufacturing, raised productivity, and led to faster modernized road, rail, and boat transportation. Among other Industrial Revolution engineers, John Smeaton (1724–1792) made key mechanical engineering improvements to both waterwheels and steam engines. Blacksmith

worker Henry Maudslay (1771–1831) led in machine-tool innovation, creating precision measuring devices, inventing metal-cutting lathes to produce standardized screws, and starting a firm that manufactured steam engines and gave young mechanical engineers on-the-job training.

The Industrial Revolution's growth of trade also rested on advances in transportation engineering and infrastructure construction. Scottish engineer Thomas Telford (1757–1834) rose from a stonemasonry apprenticeship to become the first president of Britain's Institution of Civil Engineers. Telford won renown for designing important British canals, improved roads, and bridges, including his 1826 structure crossing the Menai Straits, then the world's largest suspension bridge. Marc Isambard Brunel (1769–1849) developed tunneling technology to construct the Thames Tunnel, the first passage under a major river. His son Isambard Kingdom Brunel (1806–1859) served as chief engineer for some of England's earliest significant railroads, including the Great Western Railway, surveying routes, selecting rail gauge and rolling stock, and designing tunnels, bridges, and stations. Brunel's civil engineer expertise extended to marine engineering; he created the era's largest passenger and cargo steamships, including the SS *Great Eastern*, used to lay the first successful transatlantic telegraph cable in 1865–1866.

Engineering Systems, Education, and Professionalization in the Late 1800s

The 19th century brought continued expansion of national and global transportation routes, connected with ongoing growth and mechanization of manufacturing. Engineers played central roles in facilitating those developments. Alexander Graham Bell (1847–1922), Thomas Edison (1853–1937), Nikola Tesla (1856–1943), Guglielmo Marconi (1874–1937), and numerous others developed networks for electrification, telephone communication, and radio broadcasting. Realizing ambitious technical goals required the creation of complex systems. While many experimenters of the 1800s had investigated electricity and built arc-lighting systems, Edison had to do more than just invent a more practical incandescent bulb. Working with a team of engineers, scientists, and

mechanics at his Menlo Park, New Jersey laboratory, Edison created better electric lamps, dynamos, wires, and conduits. Edison then established companies to manufacture all those components vital to making electrification feasible and in 1882, opened Pearl Street Station in New York City, the first permanent commercial system of centrally generated electric light and power. Edison then set up hundreds of other direct-current systems across the United States and beyond, which hired hundreds of young technicians and engineers. Tesla worked for Edison before starting his own career that challenged Edison by building alternating-current electric technology. Before entering automobile making, Henry Ford gained valuable experience working for Detroit's Edison Illuminating Company.

The clear potential for new large-scale systems and machinery to have large-scale economic, political, and social impact encouraged the formalization of engineering education. Political, business, and academic leaders hailed expansion of formal training as essential in opening possibilities for economic growth and technical progress. In the United States, a key development came with Congress's passage of the 1862 Morrill Land-Grant Act to finance establishment of public colleges focused on useful training in the mechanic arts and agriculture. By offering accessible engineering education, states hoped to support entrepreneurs opening new businesses and nurture a population of male middle-class breadwinners. By the late 1800s, land-grant schools across the country combined with private schools, such as the Massachusetts Institute of Technology, to graduate hundreds of engineers each year. While many engineering curricula still stressed hands-on machine-shop work and other applied practice, the formalization of training set new standards.

Germany's Technische Hochschulen, established starting in the 1800s, combined influence of French engineering training with practical emphasis. These institutions and their graduates earned high international regard, especially in connection with Germany's world famous chemical and dye industries. Other countries similarly supported growth of formal engineering education as a tool for advancing state economic and political interests. British engineering training took root in the late 1800s and early 1900s at "red brick

universities," not coincidentally located in manufacturing centers such as Liverpool and Leeds. Spain in the 1800s established technical schools for mining, forestry, agriculture, and other fields considered essential to the civil service. Rigorous examinations and long hours of study reinforced the institutional impression of a meritocratic ideal. Russia's czars supported engineering education as a pathway to modernization. St. Petersburg, Kiev, Warsaw, and other major cities across the Russian empire set up new technical training schools in this era, modeled on polytechnic institutions in Britain, France, and Germany.

Across Europe, the United States, and elsewhere through the 1800s and into the 20th century, many men (and almost exclusively men) without college degrees continued to enter and succeed in engineering work. Those workers picked up mastery through more informal training and hands-on experience. But by the early 1900s, a growing number of large companies in particular sought to employ engineers with academic qualification. Ambitious young men hoped that engineering education could provide a secure career and upward social mobility.

Not coincidentally, a wave of professional organization in this same period allowed engineers to define themselves by discipline. In the United States, the American Society of Civil Engineers was formed around 1870, soon followed by groups for mining engineers, mechanical engineers, electrical engineers, and chemical engineers. These new societies set criteria for membership, which in turn codified expectations of experience. While politicized issues of ethics and standards sometimes raised controversial dissension, society conferences, publications, and decisions gave each discipline a voice to assert its interests with both educators and employers. Engineering groups also helped set safety standards, building codes, and quality monitoring. Nations increasingly passed laws governing the accreditation, testing, licensing, and registration of professional engineers.

Engineering Through World War II

With the expansion of industry and establishment of hierarchical large enterprises, engineers found new roles as corporate servants. Many shifted careers into management, with some reaching the

upper ranks of major firms. The early 1900s brought the creation of industrial research centers such as Bell Telephone Laboratories, Westinghouse, General Electric, DuPont, General Motors, and many others. Those institutions financed engineering and scientific research, meant to translate into a production and marketing edge. Company leaders expected tangible rewards in efficiencies and innovation in new products. Meanwhile, engineers based inside big businesses had to balance professional independence against expected loyalty to an employer, sometimes facing tough decisions about whistleblowing and concern for the public good.

The growth of big business also promoted the growth of new engineering specialties. In 1911, mechanical engineer Frederick Winslow Taylor (1856–1915) published his principles of *scientific management*, strategies for rationalizing factory design and supervising workers to maximize productivity. Although some labor elements resented and resisted the manipulation and threats of deskilling, business leaders embraced the emerging discipline of industrial engineering as promising profitable efficiencies. Henry Ford's success in institutionalizing the automobile assembly-line drew worldwide attention after 1913, and engineers built on the system of *Fordism* with further innovations in management of mass production.

In the early 1900s, as in earlier centuries, national leaders used powerful military, communications, and building technologies to facilitate conquest, colonization, and control. Numerous European and U.S. engineers worked with politicians and administrators to supervise the construction of roads, railways, telegraph lines, and water systems in remote areas of Asia, Africa, and South America. American engineers assisted with military missions in the Philippines in the early 1900s. Their careers embodied rhetoric that linked new technologies to White political dominance, and the supposedly natural advance of *civilization*. Promises of material wealth and improved well-being allowed colonizers to rationalize the harsh suppression of native peoples and serve Western political and economic interests.

Alongside the early 20th-century start of the automobile age, Orville and Wilbur Wright's 1903 success with powered flight at Kitty Hawk, North Carolina, opened up the airplane age and

ultimately the field of aeronautical engineering. Civil engineering drew widespread public attention; impressive 19th-century projects, such as the Brooklyn Bridge, completed in 1883, and 1889's Eiffel Tower set the stage for even more impressive construction, including the Panama Canal (1914), Empire State Building (1931), the Hoover Dam (1936), and the Golden Gate Bridge (1937). In the 1930s, Germany began creating its high-speed autobahn network, while engineers in the Soviet Union created the massive steel production center of Magnitogorsk. Nations invested in engineering expertise; for example, the interwar U.S. government set up the National Bureau of Standards and the National Advisory Committee for Aeronautics (precursor of the National Aeronautics and Space Administration) to foster engineering and scientific research and development.

Twentieth-century conflicts provided employment for engineers on all sides to work with national military agencies and weapons manufacturing companies in devising new weaponry, defensive technologies, and other wartime applications. World War I's destructiveness was tied to the development of powerful naval dreadnoughts and submarines, chemical weapons, tanks, and military aviation. World War II engineers and scientists created radar, rocketry, and the atomic bomb, all feeding into the technological drives of the Cold War arms race and space race between the United States and the Soviet Union. World War II also accelerated computer development in the United States and Britain, setting up postwar development of new programming languages, transistors, and microprocessors. Computer engineering thrived as marketers found new public and private customers for large-scale data handling and automation. The postwar decades also supported growth in the fields of nuclear engineering and aerospace engineering in the United States, Soviet Union, and Europe.

Late 20th- and Early 21st-Century Developments and Issues in Engineering

The post-World War II culture of technical education shifted toward the so-called engineering science, deepening emphasis on advanced mathematics, theoretical analysis, and scientific techniques. Graduate work at elite schools drew

top students from around the globe, eager to obtain the imprimatur of the most respected degrees. Further intellectual evolution fostered the rise of cross-disciplinary studies and entirely new fields, including expansion of medical engineering and bioengineering. Practices of everyday engineering work modernized, shifting away from slide rules to calculators, away from mechanical drawing to computer-aided design. But by the late 20th century, concern that education had become overly abstract led many engineering classes to move toward reinstating hands-on practice and real-life applied problem-solving. Employers expected engineering hires to master not just technical knowledge but also skills of effective communication, global teamwork, and leadership.

The 1960s and 1970s connected engineering with both highs and lows, as admiring crowds worldwide celebrated the first moon landing, but the Vietnam War and other conflicts showed the ongoing human costs of increasingly destructive weaponry. The growing environmental movement called attention to the costs of pollution and over-exploitation of natural resources. The 1980s and 1990s underlined perceptions of engineering as politically and economically crucial to national competitiveness, connecting technological expertise to productivity of manufacturing, services, and communication.

Meanwhile, the late 20th century and early 21st century brought new landmarks and new issues in engineering. Completion of impressively large global structures and infrastructure continued, including China's Three Gorges Dam (1994), the British-French Channel Tunnel (1994), and ever-taller skyscrapers. The supersonic airliner Concorde, the space shuttle, Mars rovers, the International Space Station, and other high-profile engineering and scientific landmarks drew public attention. Generations of consumers took for granted immediate access to information, messaging, and entertainment made possible by the latest smartphones, Wi-Fi access, even smart watches and virtual reality. High-tech development thrived, as the mindset of California's Silicon Valley spurred attempts to seed similar *innovation hubs* across the United States, Europe, and elsewhere. Nations including Japan, China, India, and more recently in the Middle East cultivated rapid expansion of engineering training as a shortcut to

desired economic and political transformation. Computer-driven shifts in production, communication, distribution, and sales spread associations of modernization with abundance and choice in food, clothing, housing, and personal devices. Popular culture made engineers, entrepreneurs, and innovators into new celebrities; many admired such figures as Bill Gates, Steve Jobs, Elon Musk, and Mark Zuckerberg, even as critics denounced Silicon Valley's mindset of "move fast and break things."

Innovations in technology came alongside questions and concerns about costs, benefits, and risks. Lack of investment in disaster prevention and infrastructure maintenance led to unnecessary deaths in incidents every year. Technological changes across workplaces roused fears of displacement and deskilling among both well-educated and manual employees. Easy access to online information also opened the gates to misinformation and fake news, plus difficult international debates over privacy, piracy, bias embedded in algorithms, and potential abuses of power. Engineering continued to be both a tool and a pawn of nations and regions jockeying for political and economic dominance. Secrecy, spying, and competition complicated work in nuclear, manufacturing, and computer engineering. The military-industrial complex's interest in cutting-edge technology continued to provide employment for tens of thousands of engineers worldwide, even as the power of weaponized drones and robotic warfare raised new moral hazards.

Economic and political inequities within and across nations both reflected and reinforced technological gaps; for instance, advantaged patients in well-off countries could benefit from robotic surgery, advanced diagnostic tests, and other sophisticated medical tools, while disadvantaged citizens still suffered from contaminated water, food shortages, and preventable diseases. Public and professional attention to such problems spurred debate about the social responsibility of engineering. The 1970s' *appropriate technology* movement analyzed environmental ethics and cultural fit. In later decades, advocacy groups such as Engineers Without Borders and Engineers for a Sustainable World aimed to combine professional expertise with an outward-looking activism. Concerns about climate change drove growing

21st-century investment in green design and renewable energy engineering, alongside debates about carbon sequestration technology and future radical geo-engineering. Yet as for centuries, the pathway of technological development was never predetermined. Human choices, uncertainties, cultural constraints, and political disagreements shaped the terms of engineering work and complicated decision-making about desired outcomes. Individual and social conditions even affected which matters were defined as engineering problems to be solved and how.

Meanwhile, 20th- and 21st-century campaigns aimed to open more opportunities in engineering for women and other historically underrepresented groups. For centuries, technical careers had remained almost universally the province of White men. Engineering's historic ties to the military, field projects, and corporate ranks blocked access for most women. Rhetoric promoted engineering as a masculinized culture, valorizing daring heroes who built railroads across deserts, roads through jungles. Building and model construction toy kits explicitly encouraged boys to enjoy tinkering, promising that hands-on play would lead young men into engineering jobs.

During the early 1900s in the United States, Canada, and Europe, a handful of women had pressed ahead to earn engineering degrees at the few schools willing to accept them. Many faced isolation, skepticism, ridicule, or opposition from parents, high-school teachers and counselors, and both male and female classmates. Engineering faculty, deans, and employers often openly doubted whether female students could succeed. For decades, major engineering organizations such as the American Society of Civil Engineers refused to accept women. Lillian Gilbreth, who had worked hard to establish a strong reputation in industrial engineering, still confronted an uphill battle to win full membership in the American Society of Mechanical Engineers.

In the 1950s, women still comprised less than one percent of engineers in the United States and many other countries, though substantially more in the Soviet Union. In Western nations, the small but growing ranks of female engineers organized to support each other and encourage more young women to consider engineering careers. A handful

of female engineering school faculty and staff, together with male allies, offered psychological and practical support in what remained a frequently chilly and even toxic climate. Female students who persisted to earn degrees confronted extra hurdles in finding employment. Hiring committees questioned women about when they would get married, doubted whether a female engineer could think about mechanical details "like a man," and offered salaries distinctly lower than men's.

In the late 1960s and 1970s, feminist movement mobilization led women in engineering studies and careers to mobilize to confront those hiring biases, sexual harassment, and the challenges of juggling work and family. By the 21st century, major engineering programs, professional organizations, and other leaders in the United States, Europe, Asia, and elsewhere mounted and joined campaigns for diversifying engineering. Global corporations, governments, schools, and other parties launched multimillion-dollar initiatives to expand access to engineering and computer education for more youngsters from previously underrepresented groups. Female engineers continued to report harassment and discrimination from employers and coworkers in Silicon Valley and other job sites. For complex reasons, women's representation in engineering still varied dramatically between different countries and across technical disciplines. But discussions of social justice and embedded bias aimed to reshape engineering culture for a modern age.

ENVIRONMENTAL STUDIES

Environmental Studies as an academic discipline is relatively new, with higher level degree options only available for the last few decades. Ironically, for most of human intellectual history, academics did not fragment into specialization within just one single discipline. With rapid increase in knowledge across the academic spectrum produced since the

Enlightenment, the trend toward specialization continues at an accelerated pace. Thus, the efforts of those who synthesize, integrate, and draw connections between disciplines now seem new. Let it suffice to say that the term *environmental studies* has only recently been coined, whereas the ideas it addresses have deep traditions. The core of environmental studies seeks to emphasize the interrelations both between natural systems and between human beings and natural systems. Unlike other academic disciplines, inherent within environmental studies is the strong ethical belief that human–nature interactions ought to be as benign as possible for both humans and nature. The fact that this is often not the case drives a sense of urgency for change in our current ways of interacting with nature that underlies contemporary environmental studies.

Because environmental studies emphasize dynamic interaction between human and natural systems, it is necessary to integrate and span across both the natural sciences and the social sciences and to include methodologies that range from extremely quantitative to highly qualitative. This wide umbrella can be perceived as both strength and weakness for environmental studies, since the breadth of knowledge acquisition must at some point sacrifice a level of depth in any one discipline. That said, one thing is certain; today's generations face complex problems at multiple scales, ranging from global climate change to local sources of pollution. But any solutions to these problems require understanding political, economic, historical, and cultural forces as well as impacts to biogeochemical systems, and often, these problems persist specifically because people with different aspects of understanding and knowledge do not talk to each other or use the same vocabulary, nor do they understand how human actions impact the natural environment.

Given the interdisciplinary and integrative nature of environmental studies as a discipline, it is common practice for environmental specialists to choose from a wide array of theories developed by other disciplines and utilize them in new or innovative circumstances toward an environmental end. Being theoretically promiscuous often results not in scandal, alienation, or outrage but in innovation, curiosity, and creative problem-solving. Theoreticians within most disciplines spend their

intellectual energies seeking to define, refine, and expand the core ideas that make a specific academic pursuit, but the discipline of environmental studies is uniquely situated to adapt theories across a variety of disciplines, expanding not at the core but at the leading edges between disciplines. In this unmapped territory that most traditionalists of any single discipline consider to be populated by heretics and renegades, entirely new and creative thinking, which transcends the constraints of any one discipline, becomes possible. Indeed, this creative and transcendent thinking is not just possible but desperately needed if we are to solve the pressing environmental issues that surround us. This entry focuses first on some background ideologies that set various foci for environmental studies and then traces some cultural developments that have resulted in the discipline we now have, several strands of which are discussed in the last five sections.

Anthropocentrism

The concept of *anthropocentrism* gives a name to the deeply embedded belief that human welfare matters most, and whatever interactions occur between humans and the natural environment become relevant only as they benefit humans. This often takes the form of material benefits that increase economic prosperity; raise the human standard of living; entail the capture, storage, and use of natural resources; and most specifically focus on improving the *condition of man* as a desired outcome. Although it may seem that this describes most people in their daily activities, it is worthwhile to note how strong a role cultural identity plays in determining whether, or to what degree, a person, group, or nation stresses anthropocentrism.

In America, anthropocentrism often coincides with other beliefs that are not necessarily the same but have overlapping agendas, such as individualism, private property, the Judeo-Christian tradition, and capitalist economic values. In order to prioritize the welfare of human beings as the basis of all activities, this usually means accruing wealth and maximizing the right of the individual to behave in any manner that improves individual conditions—regardless of impacts upon others or the natural environment. The motivation to be anthropocentric can often tie deeply with religious

beliefs predicated on being chosen as a favorite creature of God in his kingdom and/or the belief that humans were put on Earth to tame nature. Other cultures and countries have far different but equally deeply rooted views on how humans ought to interact with nature. Cultural perception of nature diverges most sharply from anthropocentrism in regions dominated by animist and tribal religions and in the presence of the Asian religions of Buddhism and Shinto.

Ethnocentrism

Similar to anthropocentric views but on a smaller scale, *ethnocentrism* prioritizes those things that improve a subgroup or ethnicity of people. In this case, humans in general matter less than one's own tribe, or group of people, but the idea is essentially the same. Efforts or actions taken to improve the standard of living, wealth, or well-being of one group would downplay or ignore residual impacts to other groups of humans or to the natural environment. This more localized prioritization of some people's benefit (usually at the expense of others) has been an underlying cause of warfare, famine, and environmental disasters since time immemorial. For instance, looking at water management, we see many regional tensions due to ethnocentric values. Israel declared a buffer zone of military occupation in southern Jordan, but it also drilled several deep wells to procure much coveted water in a desert environment—specifically at the expense of those who live in Jordan. Similarly, U.S. agricultural activities degrade the water quality of the Colorado River as it flows south into Mexico, but many Americans do not consider the burden this puts on Mexico, nor does the U.S. government seriously address appeals by Mexico to rectify the situation.

Ecocentrism

In contrast to both anthropocentrism and ethnocentrism, *ecocentrism*, also known as *biocentrism*, prioritizes natural systems and sees human beings as just one species among many. Thus, it is the ecosystem as a whole that must be considered first, when decisions are made and actions are taken. In the ecocentric view of the world, protection of natural systems is paramount, even if some

humans suffer setbacks or are constrained from maximizing their potential wealth. For instance, given the choices between clear-cutting a forest to maximize the profits gained in selling the lumber or some other land use, an ecocentric decision might be to only selectively cut trees in order to thin out the forest and sustain its long-term health. Clearly, a person cannot simultaneously be anthropocentric and ecocentric, since the values are often mutually exclusive. One cannot save a forest and simultaneously clear-cut it to develop the land. However, one dilemma that environmental studies centers on is the tendency of humans to think one thing and do another. In reality, most people live with some contradictory impulses toward both anthropocentrism and ecocentrism, and finding a balance between these conflicting impulses presents a deep challenge to daily living and short-versus long-term metrics of success, value, costs, and benefits.

Capitalism and Exploitation

The idea of commerce and trade for profit goes back thousands of years. But not until the convergent evolution of capitalism, paper currency, and changes in political theories of value and property, did we see massive transformation in the political economy and a concomitant rise in use of resources that now exists in modern capitalism. Feudalism as a system of land tenure, social organization, and economy dominated for more than 1,000 years before its dismantling, which began in Europe in the 16th century. During this time, both the numbers of people and their combined ecological effects remained stable with a relatively low impact on the environment. As agrarian capitalism gave way to mercantilism, and then industrial capitalism, theories of philosophers John Locke and Adam Smith established the fundamental ideas of industrial capitalism, and it is this system that has dominated political and economic thinking for the last 200 frenetic years of expansion.

A core idea of capitalism assumes that all participants are rational actors, who will seek to utilize the resources at their disposal to maximize their personal economic gain, and it is that instinct which drives the laws of supply and demand. It is upon these deeply embedded ideas that industrial

capitalism feeds the desire to continually accumulate more wealth. Of course, natural resources form the basic raw ingredient in this philosophy of political economy. Nowhere among the basic premises of industrial capitalism is there to be found any discussion of limits on accumulation of wealth, the consumption of finite resources, or the environmental damage done as a residue of accumulating wealth and exploiting resources. But an economic system predicated on endless exploitation of natural resources generates incentives to maximize the exploitation of such resources. And after two centuries of resource exploitation feeding the system of industrial capitalism, two realities helped propel the rise of environmental studies. First, the planet is, of course, finite and so is most of the resources we exploit, so our current system is not sustainable. And second, the rapid rise in resource exploitation driven by industrial capitalism causes equally rapidly rising environmental residue in the form of air, water, and soil pollution and imperils ecosystems all over the globe.

Conservation

Out of the humanist impulse came the first widespread conservation movement, emerging in the United States in the late 1800s. *Conservation* brings together ideas from economics, such as scarcity, with those of agriculture and animal management, such as the need for predictable feed stocks. When resources become scarce, then conserving what is left becomes a logical and ethical priority. For the conservationist, one need not wait until the point of scarcity; rather, conservation is seen an ethical way to live no matter how many resources remain. The idea is most commonly embodied by Gifford Pinchot (1865–1946), the first head of the U.S. Forest Service, who famously made decisions based on the greatest good for the greatest number of people. The conservationist sees the need to use our natural environment to improve the human condition, but those benefits should be made accessible to the largest possible number of people and with minimal waste, so that there will continue to be resources for use in the future. This is considered by many to embody the idea of enlightened self-interest. If natural resources get squandered, many of them cannot be replaced, so thinking in terms

of long-term sustainability of the resource makes more logical sense than exploiting as much as possible now, for short-term gain. Although almost nobody disagrees with the underlying concept that conservation makes sense, exactly where to draw the line between responsible use and overexploitation of any resource comes down to shifting social priorities and tensions related to who gains from resource exploitation and who does not.

Preservation

Going farther than conservation, *preservation* as a philosophy or mode of thinking promotes the idea that some things in nature must be preserved and never used by humans, on the grounds that their existence adds to the aesthetic beauty, the grandeur, stability, and power of nature. Natural systems must be protected from abuse, by preserving them from any exploitation at all. There is no middle ground for preservationists, perhaps the most famous of whom was John Muir (1838–1914), who fought a lengthy political battle of wills with Gifford Pinchot over whether the Tuolumne River in California should be dammed to provide drinking water for San Francisco after the 1904 earthquake. To dam the river would mean flooding one of the most exquisite valleys in America, and Muir believed passionately that the valley's intrinsic beauty and value could never be compensated for once it was lost under the rising water of a reservoir. In the end, it is arguable that Muir lost the battle but won the war. While the Hetch Hetchy dam did get built, the political explosion and fallout that followed set off the first widespread efforts at environmental preservation in the United States. One remnant of that fight remains in the form of the Sierra Club, a nonprofit organization that is now nationwide, started by John Muir at the turn of the last century. The concept of preservation now has a persistent voice in our conversations about environmental issues, even if there may be a lack of clarity on just what or how much nature should be preserved.

Tragedy of the Commons

In 1968, Garrett Hardin, an ecologist, set off a storm of debate across several fields of study with an article in the journal *Science* titled “The

Tragedy of the Commons,” in which he reconsidered the social question of population issues, but with a focus on economic theory and natural resources. To the present day, his argument continues to be a theoretical touchstone for much of the environmental and natural resource communities, while its implications echo outward to many disciplines. According to Hardin, when individuals have unlimited access to natural resources, they will inevitably act in their best interests to maximize their own utility; that is to say, maximize their ability to *use* the raw materials of the environment to satisfy needs or wants. If each individual profits by exploiting as much of the resource as possible, but the group as a whole shares in the negative utility caused by depletion of the resource, then each individual would be compelled to overuse the resource, since the individual gains all of the profit but shares only a fraction of the impact felt from the degraded resource.

In his article, Hardin illustrated his point using the example of common grazing lands for herders. Each individual will seek to maximize his profit from the resource, so it would be in their best interest to add one more sheep to their herd. Every herd owner does the same thing, and the logic appears sound. Each individual herd owner increases their own herd, thus their profits, and every individual gains wealth. The dilemma comes when the common resource, in this case the common grazing area, becomes degraded to the point that it can no longer be used at all, and the grazing economy collapses. In fact, the herders are locked into a system that compels each individual to grab as much of the resource as possible at ever increasing rates. In the case of the herders, if an individual does *not* add more sheep to their herd, then other competing individuals will simply add more and the herder will miss the opportunity to maximize utility. The hard-hitting message contained in the example rests with the realization that it is possible for each individual to gain by acting in their own self-interest, while the group as a whole loses in the end.

This exposes a dangerous but previously unaddressed problem at the heart of capitalism and the neoliberal economy. One of the fundamental tenets of neoliberal economy assumes that all actors seek to maximize their own utility and

should behave accordingly, and this is the basis of rational actions. But, if all actors behave rationally, then they will seek to maximize their utility in the market, even as the resources upon which the economy depends become degraded then depleted, and eventually disappear completely. This leads to total economic and ecologic collapse, precipitated by the destruction of our natural environment. Hardin applied this logic to the threat of overpopulation, viewing the planetary carrying capacity as the commons, and each new person to feed as a new drain on the common resource of the planet, and concluded that there is no technical solution to this dilemma. In his analysis, Hardin separated out those problems which might have a technical solution, or a change in the techniques or science applied to them, from other problems for which there is no technical solution; this latter category requires a change in our morality or human values to find a solution. From this dialogue, efforts to clarify and express just what the range of human values were resulted in the widespread use and discussion of the terms anthropocentrism, ethnocentrism, and ecocentrism. Clearly anthropocentric values should lead economic actors to maximize their own profit in the short term, even at the cost of destroying our natural environment over time and would spiral toward a tragedy of the commons without pause.

Critics of Hardin, most famously Elinor Ostrom, point to counterexamples, where a tragedy of the commons was avoided, and suggest that it is not as prevalent or as inevitable as Hardin would have us believe. She and other critics point to examples in which cooperative behavior results in collective restraint and sustained use of resources, since it is understood that both individuals and the collective benefit from this action. Thus, if economic actors share ecocentric values, then they would cooperate enough to collectively restrain the total destruction of the environment, thereby providing the resources they share, need, and can sustainably use. Others criticize Hardin for being historically inaccurate by failing to acknowledge the demographic transition or to distinguish between common-pool resources and open-access resources.

The *tragedy of the commons* metaphor aptly illustrates that unlimited demand in a world of finite resources leads to overexploitation and

ruination of our environment—given open access to common resources. *The tragedy of the commons* theory sparked debate in circles of thought as wide and seemingly unconnected as game theory, psychology, cultural anthropology, and strategic model building, as well as its more obvious links to environmental studies, geography, political science, ecology, and economics. The theory stands as an easily graspable conceptual model for a wide array of resource-related and environmental issues based on the dilemma of finite resources such as water, forests, fossil fuels, and arable land, for which we seem to have an ever increasing number of users. Environmental scholars and activists remain staunch, however, in their cries for vigilance, and for the need to rework our priorities and our mechanisms of constraint. They believe that the scale and persistence of environmental degradation speaks for itself loudly, pointing in no uncertain terms toward global tragedy and environmental calamity if the pace and manner of global development, and the values of endless consumerism, are not curtailed—and quickly.

Gaia Theory

Developed by the chemist, physician, and environmentalist James Lovelock and the microbiologist Lynn Margulis in the 1970s, *Gaia theory* suggests that the biotic elements of Earth interact with inorganic elements of our environment to form a self-regulating interconnected system that contributes to maintaining the conditions for life on the planet. Named after the Greek goddess Gaia, this concept, also known as the *Gaia principle* and *Gaia hypothesis*, suggests that organisms coevolve with their environment. In other words, biota influence aspects of their inorganic environment, such as temperature or atmospheric conditions, and that altered environment in turn influences the development of biota; together, these forces generate a stable system, described as *planetary homeostasis*. The interactions are complex, but here are two simplified examples used in Gaia theory: air temperature and atmosphere. Since the beginning of life on planet Earth, there has been a 25% increase in the amount of heat from the sun, but the surface temperature has remained virtually constant. Also, our atmosphere consists of roughly 79% nitrogen, 20.8% oxygen,

and 0.03% carbon dioxide (CO₂). This highly unstable mix of reactive gases could not be maintained without constant replacement and/or removal by the Earth's biota. Earlier in Earth's history, the atmosphere contained higher levels of CO₂ and these CO₂ levels produced a greenhouse effect that warmed the planet. Later, biota on the planet has produced increasing amounts of oxygen and methane, via cycling through oceans and rocks; these changes in the atmospheric chemistry have been maintained by evolving species. Now, CO₂ is minimized by pumping down of carbon through the biota. Without the presence of greenhouse gases in the atmosphere, scientists estimate that our planet's surface temperature would be approximately 19°C (66.2°F).

The idea of a planetary homeostasis influenced by biotic factors already exists and is studied by scholars from academic disciplines including ecology and biogeochemistry, or Earth system sciences. However, a unique element of Gaia theory puts forth the assessment that this homeostatic balance is pursued actively, if unconsciously, to achieve optimum conditions for life on the planet—even if external forces threaten that stability. Thus, taken to its logical conclusion, the theory implies that the biotic balance with the regulatory systems of the planet, such as oxygen in the atmosphere or salinity in the ocean, will maintain balances needed to optimize a biogeochemical balance, even if external human activity threatens that equilibrium. Gaia theorists believe that humans could find themselves one day headed toward extinction as a species but that the planet as a whole would still remain, with its regulatory systems intact. Gaian theory essentially posits that the Earth is in some complex sense *alive* and functions as an intricately interconnected singular entity.

This theory has generated much speculation and debate along the academic spectrum, from philosophers to Darwinists. Philosophers use Gaia theory to begin asking fundamental questions about teleology, the meaning of *living*, and the need for consciousness in order to act in unison. To achieve this, reconsiderations of basic ethical values or concern for nonhuman and even nonliving components of the natural world would be required. The Gaian worldview rests on the notion of large-scale cooperation rather than competition as a driving force and simultaneously suggests that

the planet's natural systems are not just interconnected but also function toward a common purpose—stabilization. On the other end of the spectrum, staunch Darwinists critique the Gaia theory and suggest that evolutionary strategies could never account for complex interaction among nonsentient biota at such large scales. For Darwinists, there is simply no plausible way that the feedback loops Lovelock says work to stabilize the planet could have evolved. For Darwinists, some mechanism must be shown to control the processes described, and if they see no mechanism at work, they see no larger cohesive end. Gaia theory has also set off arguments among scientists about what it means to be *living*, and Darwinist critics note that since Gaia cannot reproduce itself, it fails to meet one of the key components in the accepted definition of *living* among the scientific community.

Sustainability

This concept is linked to, but not the same as, the Gaia theory. The term *sustainability*, a recent addition to our lexicon, has become so widely used and with different definitions that the term may have lost some of its original power as an idea. The most prevalent definitions all agree that in order to for the way we live to be sustainable, we must treat our natural environment in ways that ensure we have enough resources left that future generations are not significantly disadvantaged. Although there may not be a consensus on what living *sustainability* entails, there is agreement on what it is not. Overexploitation of resources and rampant environmental degradation are signs that we are not living within our ecologic means. Capitalist economies are based on individual incentive to maximize profit, which necessitates exploiting more and more resources, which generates ever more pollution. By predicating economies and policies on nonrenewable fossil fuels, we are essentially spending the environmental bank accounts of future generations to satisfy this generation's lifestyle, which is clearly unsustainable.

Pathways toward achieving sustainability, as currently defined, have become vaguer, more varied, and more contentious. Some critics of the status quo suggest that we can put off choices regarding whether or how to include future

generations in our decisions by implementing simple conservation techniques. If priorities changed at every scale from individuals to federal governments to include conservation, thus reducing the detrimental aspects of capitalism, we could delay reaching the limits of fossil-fuel-based economies for several more generations as we think constructively about what to do.

Carrying Capacity

Borrowing a classic concept from biology, practitioners of environmental studies continually grapple with the quantitative and qualitative metrics of *carrying capacity*, or the amount of population that an ecosystem can sustainably support without overtaxing the resources and balance of life within the ecosystem itself. Any discussion of sustainability must be framed by asking pertinent questions about just how many people can be sustained and at what scale, or at what level of existence. The problem rests with the reality that we simply do not know what the biologic carrying capacity of the planet is, and we are not likely to know until we pass the threshold which the planet can support, then see the crash in population due to our having reached this tipping point and not stopped. This is not a number or proportion that can be easily estimated, and even if we could do so, that begs the question of the standard at which the population would live. The carrying capacity would be quite different if everyone were at the same standard of living as people in Guatemala, for example. And it is not even possible today to have the entire planet live the same lifestyle as residents of the United States, which contains less than 5% of the world's population but consumes well over 25% of all its resources each year.

Even without knowing the precise number of people this planet might sustain, many observers base their critiques of the status quo on maldistribution of resources and vast inequities in wealth and poverty across the globe. They recognize that questions of sustainability must address *how* people live, not simply *how many* people live on the planet. A formula borrowed from geographers illustrates this idea: $I = P \times A \times T$ estimates total Impact by multiplying Population times Affluence and Technology. For instance, if a country is quite affluent, then it will probably have access to much

technology, and the overall impact of each person will be far greater than the relative impact of a single person elsewhere. A new baby born in the United States last year is expected to consume 25 times more resources than a new baby born in Burma, based on this equation. Thus, small but affluent populations have total environmental impacts much larger than their population alone would suggest. Similarly, very populous but poor countries without access to technology languish at the bare edge of subsistence using far fewer resources than their numbers alone would predict.

This formula does not account for everything, and critics are quick to point out counterexamples, which do not fit neatly into this formula. How does $I = P \times A \times T$ deal with countries that utilize technology to develop renewable resources, for instance? Another situation not easily accounted for is that of a country that uses technology, but that country's population does not acquire affluence associated with the level of technology. This lopsided situation occurs in underdeveloped nations with large labor forces working for low wages in outsourced manufacturing jobs that produce items consumed by developed countries.

Environmental Justice

A new and rising trend that environmental studies scholars have helped bring to the forefront of conversation is *environmental justice*. The idea of environmental justice centers on the imbalance between those who benefit from using resources versus those who live with the residue of that use, or the environmental degradation generated as a byproduct of exploiting, refining, distributing, and consuming natural resources at all phases. Thus, there is a need to find justice for those who disproportionately bear the burden of others' comfort. For instance, only those who are too poor to move elsewhere will live near city dumps, toxic brownfields, or the noise, smell, and filth associated with factories. There is also a racial component to environmental justice in the United States, due to the high numbers of minorities who are lower on the socioeconomic ladder and thus have fewer options to relocate when faced with pollution, toxic health hazards, or even an abundance of ugly industrial buildings in their proximity. Environmental justice advocates seek to redress these imbalances, often through the

legal system and politics, with varying amounts of success. One intriguing new direction in this rapidly evolving subdiscipline rests with geographic inaccessibility and the persistence of poverty. Wealthy people take the best land, with the best resources, leaving only marginal lands for others, which accelerates environmental degradation specifically because the areas were marginal to begin with, then become overexploited. Once the marginalized ecosystems lose their fragile equilibrium, then a cycle of degradation ensues, leading to overexploitation, which in turn creates environmental destruction, such as mudslides, desertification, and famine, which leads further to desperation, and this continues or even accelerates the overexploitation. Such is the situation in areas such as the slums of Karachi, Pakistan, and nearly the entire Ganges River delta region of Bangladesh.

Deep Ecology

Initially coined as a term by Norwegian philosopher Arne Naess in 1973, *deep ecology* draws together ideas found in ecocentrism, Gaia theory, and environmentalism. Naess claims that deep ecology is merely the philosophical extension of the scientific foundations of ecology. Essentially, humankind is not above nature but merely one part of the larger ecologic system that is the living Earth. At its core, deep ecology stresses wilderness preservation, human population growth limits, and the need to *live simply* on the planet or, in other words, to leave a light ecological footprint. Deep ecologists contend that unbridled industrial capitalism in itself is the major problem escalating exploitation and destruction of the natural world, citing rapid species extinction, reduced biodiversity, and accelerating climate change; they believe the only moral response to our conundrum lies in fundamentally changing the way we structure our political economies. Deep ecology can be seen as the core component of larger movements such as the rise of *green party* politics, and contemporary *eco-spirituality*, which runs counter to the anthropocentric Judeo-Christian traditions. In deep ecology, we see a philosophic repositioning of the concept of *self* as well as the wider metaphysical implications of humans as just one piece of a single but interconnected unfolding reality.

Some critics see deep ecology as a philosophy that denigrates or dislikes humanity, since the central tenet revolves around ecosystem health and humans as just one piece of this system. Needless to say, deep ecology presents the most significant challenge to the dominance of industrial capitalism, anthropocentrism, resource exploitation, and large governments since the beginning of capitalism.

EPISTEMOLOGY

Epistemology is a branch of philosophy that explores knowledge or how people know what they know. Epistemological questions include “What counts as knowledge?” “How is knowledge acquired?” “To what extent is knowledge provable?” and “What is the relationship between the knower and what is known?” Ways of knowing have been contemplated and contextualized broadly across many disciplines through discussions related to reason, emotion, perception, and language and, in more specific terms, via discussions about the method of tenacity (e.g., superstition), method of authority (e.g., religion), method of intuition (i.e., philosophy), and method of science. The *method of tenacity* believes something is truthful despite evidence. The *method of authority* is accepting a truth to be true because someone said it was so. The *method of intuition* is accepting a truth to be true because it is rooted in logical reasoning, yet no empirical support exists. The *method of science* seeks to find truth through observable events.

Epistemological questions about knowledge and theory building are often accompanied by three related philosophical inquiries and/or claims: ontological, praxeological, and axiological. *Ontology*, or the study of reality, is interested in answering questions such as “What can be said to exist?” and “What are the meanings of beings?” *Praxeology*, or the study of human action, is interested in questions such as “What is the practice of the practical argument?” *Axiology* makes claims or asks questions related to the worth of knowledge or theory by asking questions such as “What is the role or function of scholarship in society?” Additionally, methodological questions/concerns, or philosophical claims about what methods are appropriate and/or effective given the theory or inquiry, must be addressed.

This entry comprises seven main topics that help to define and contextualize epistemology. First is an overview of its history and the role that epistemology plays in theoretical inquiries. Then, a division of epistemology into two main camps, *internalism* and *externalism*, is discussed followed by another main division, here of epistemological accounts of the structure of knowledge as either *foundationalist* or *coherentist*. Following these stage-setting discussions, consideration is given first to how epistemological concerns shape and are shaped by the research paradigms of inquirers, second the meta-epistemological orientation of objectivism and subjectivism, third the role of epistemology in self-reflection, and finally of the main tenets of feminist epistemology.

The Historical and Theoretical Role of Epistemology

The word *epistemology* derives from the Greek language: *episteme* (know) and *logos* (logic). The philosophical study of epistemology dates back to antiquity when the Sophists questioned the possibility of objective truth, Plato argued that absolute or exact knowledge existed, and Aristotle held that experience was the key to knowing. The introduction of René Descartes’s (1596–1650) book, *Meditations*, in 1641 demarcated a shift away from Aristotelean ways of knowing by introducing a more modern philosophy centered on skepticism or the method of doubt. In the late 1700s, Immanuel Kant (1724–1804) introduced

a newer philosophical shift in epistemology by challenging both empiricism and rationalism. His critical work deconstructed the two competing belief structures of the Enlightenment era: Knowledge was acquired through either reasoning (a priori knowledge; rationalism) or sense perception (a posteriori knowledge; empiricism). Beginning in the 19th century, as scholars attempted to reconcile rationalism and empiricism, discussions about how each approach or understanding of knowledge creation should address questions of justification and description emerged. The debates about justification, in particular, are covered in more detail in the following section of this entry.

Epistemological questions about the nature, scope, and function of knowledge are primary to the development of theory. In fact, it is an essential precursor to theoretical perspectives, methodological considerations, and method choices across many social scientific and humanistic academic disciplines. The *tripartite theory of knowledge* suggests that knowledge is a “justified true belief” More specifically, belief, truth, and justification are all necessary factors of knowledge—and of theory building. That is, unless one believes something, they cannot know it; if one knows a thing, then it must be true; and in order to know a thing, one must have a good reason for doing so (it is not enough to believe it is true). Thus, theories about human phenomena (or any phenomenon) are rooted in the basic desire to explain, understand, predict, and/or control individual and/or shared realities through belief, truth, and justification.

Internalism and Externalism

The internalism–externalism debate lies near the center of modern discussions about epistemology. The basic idea of internalism is that justification is solely determined by factors that are *internal* to an individual. Externalists disagree, asserting that justification depends on additional factors that are *external* to an individual. The rise of this debate coincides with the rebirth of epistemology after Edmund Gettier’s famous 1963 paper, “Is Justified True Belief Knowledge?” In that paper, Gettier presented several cases to show that knowledge is not identical to justified true belief. Cases of this type are typically referred to as *Gettier cases* and

illustrate *Gettier problems*. Traditionally, Gettier cases show that one can have internally adequate justification without knowledge. The introduction of the Gettier problem to epistemology required scholars to rethink the connection between true belief and knowledge, and the subsequent discussion generated what became the internalism–externalism debate over the nature of justification in an account of knowledge. Internalists maintained that knowledge requires justification and that the nature of this justification is completely determined by a subject’s internal states and/or reasons. Externalists argued that either the nature of justification is not completely determined by internal factors alone or knowledge does not require justification. The internalism–externalism discussion engages a wide range of epistemological issues involving the nature of rationality, the ethics of belief, and skepticism.

The Structure of Knowledge: Foundationalism, Coherentism, and Reliabilism

The three most prominent theories of epistemic justification are *foundationalism*, *coherentism*, and *reliabilism*. All three are meant to address the problem known as the *regress problem of justification*. More clearly, if individuals think of epistemic justification in inferential terms (i.e., for every justified belief there must be at least one other justified belief on which it is based, which must in turn be based on at least one other justified belief, etc.), then there must be an infinite regress of justified beliefs—and individuals do not seem to have the ability to make sense of an infinite chain of inferences.

Foundationalism is an attempt to stop this regress of justification by positing the existence of foundational or *basic* beliefs (i.e., justified without being inferred from other beliefs). Because basic beliefs are justified, they are able to confer justification onto other beliefs that can be inferred from them. Coherentism is a rival theory of justification. Unlike foundationalists, coherentists reject the idea that individual beliefs are justified by being inferred from other beliefs. Instead, according to coherentism, whole systems of beliefs are justified by their coherence or the idea that a belief set is coherent to the extent that it is

consistent, cohesive, and comprehensive. Reliabilism is an alternative theory of justification to foundationalism and coherentism. According to reliabilism, a belief is justified based mainly on how it is formed—thereby removing the burden of deciding whether a belief is justified based on whether or not it is appropriately related to other beliefs. Essentially, the reliabilist holds that a belief’s justification depends on whether it is formed using a reliable or an unreliable method (e.g., if perception is a reliable method for forming beliefs, then beliefs based on perception are justified).

Research Paradigms

In the social sciences and humanities, epistemological concerns become paramount depending on the paradigm the researchers are positioned within. In the social sciences, *postpositivism*, *interpretivism*, and *critical theory* comprise the primary paradigms. The postpositivist paradigm, largely informed by the French philosopher Auguste Comte (1798–1857), emphasizes observation and reason as means of understanding human phenomena. This paradigm is anchored by the underlying assumptions of determinism, empiricism, and generality—and the belief that true knowledge may be obtained by observation and experiment. *Determinism* means that events are caused by other circumstances; and hence, understanding such correlatory and casual relationships is necessary for prediction and control. *Empiricism* aims to collect verifiable empirical data in support of theories or hypotheses. *Generality* is the process of generalizing the observation of the particular phenomenon to the larger population. The postpositivist paradigm systematizes the knowledge-generation process with the help of quantification via survey, content analyses, and experiments.

Interpretivism emphasizes that social reality and truth/reality are multilayered and complex, and a single phenomenon is likely to have multiple interpretations that may only be understood by probing the various unexplored dimensions of a phenomenon rather than establishing specific relationships among variables. It is grounded in three major areas of study: *phenomenology*, *ethnomethodology*, and *symbolic interactionism*. All

three emphasize human interaction with phenomena in one's daily life and suggest qualitative rather than quantitative methodological choices. *Phenomenology* is a theoretical perspective that suggests that individual behavior is determined by the experience of an individual's direct interaction with a phenomenon. During this interaction, individuals attach meanings to different actions and or ideas and thereby construct new experiences. *Ethnomethodology* deals with the world of everyday life. According to ethnomethodologists, theoretical concerns center on the process by which commonsense reality is constructed in everyday face-to-face interactions. This approach studies the process by which people invoke certain *taken-for-granted* rules about human behavior and give it meaning. Symbolic interactionism focuses on trying to understand and interpret interactions that take place between individuals. The peculiarity of this approach is that human beings *interpret and define* each other's actions instead of merely *reacting* to each other's actions. Human interaction in the social world is mediated by the use of symbols like those of language, which help human beings to give meaning to objects. To understand and explain phenomena, the interpretivist paradigm uses ethnography, case studies, and biographical data collection as its primary methods.

Critical theory is a tradition that assumes reality is created and shaped by social, political, cultural, economic, ethnic, and gender-based forces that have been reified over time into social structures that are taken to be natural or real. Additionally, critical theorists state that we as individuals, including researchers, cannot separate ourselves from what we know and this inevitably influences inquiry. What can be known is inextricably tied to the interaction between a particular investigator and a particular object or group. Critical theory is particularly concerned with the role of power in all interactions—and that the perpetuation of the subjective—objective controversy is problematic. Rather, critical theorists suggest that *objective* practices are often the most *subjective*. Methodological approaches tend to rely on dialogic methods—that is, methods that combine interviewing and observation with approaches that foster conversation and reflection. This reflective dialogic allows the researcher

and the participants to question the *natural* state and challenge underlying and often systemic power structures.

Objectivist and Subjectivist Positions

Because all theories are based in metatheoretical assumptions, it is important to understand two key epistemological positions. First, the objectivist position, which was dominant in physical and social science traditions throughout the 20th century, espouses empiricist and rationalist ideas. Objectivists generally believe that reality exists outside of and apart from the individual. From this perspective, a knowable reality awaits discovery through the scientific method. As such, objectivists explain social phenomena almost exclusively through causal relationships. By contrast, the subjectivist epistemological position assumes that human beings actively create knowledge. From this frame, because knowledge is cocreated in social interaction, it is situated and highly contextual. Subjectivists favor interpretive processes when developing theory. Rather than seeking to explain social phenomena through universal laws, subjectivists aim to describe and understand various contexts wherein knowers and the known function. The objectivist and subjectivist positions serve different interests, and each of these positions differs significantly from a third epistemological stance that considers the political nature of knowledge.

Self-Reflection as Epistemological Project

Renowned critical theorist Jürgen Habermas outlines a *politics of epistemology* (Mumby, 2001) to highlight the relationship between power and knowledge. Demonstrating that scientific knowledge is but one type of knowledge in the world, Habermas identifies three *knowledge constitutive* interests in society—the first two of which align with the objectivist and subjectivist positions, respectively: (1) *the empirical-analytical cognitive interest*, rooted in technical goals to predict and control both the physical and social world; (2) *the hermeneutic-historical cognitive interest*, rooted in goals to understand situated human activity; and (3) *the critical-emancipatory cognitive interest*, which posits knowledge as a

self-reflexive process through which to uncover hidden but pervasive power that shapes taken-for-granted assumptions about reality. Critical theorists thus differ from objectivists and subjectivists in that their epistemological commitments view knowledge as a means for transformation and emancipation. Habermas (1971, p. 197) explains, "In self-reflection, knowledge for the sake of knowledge comes to coincide with the interest in autonomy and responsibility." For critical theorists, knowledge is political. That is, knowledge (and the ways it is created and expanded) is intrinsically linked to ideology that can function as a form of control. Antonio Gramsci (1891–1937), Marxist theoretician, stated that this form of control is also known as *hegemony*, a process in which dominant individuals and groups lead others to accept and unconsciously exercise subordination as natural. While there are many varieties of critical social science, critical theorists are united in their goals of providing normative theories as the basis for social inquiries and effecting social change.

Feminist Epistemology

A prominent and increasingly influential area within the critical tradition is feminist studies. Feminist studies, too, encompass a wide range of viewpoints. In general, theorists working in feminist studies share an approach to epistemology that recognizes the connection between the knower and the known. Standpoint feminists, for example, argue that all women do not speak with a single voice, and they caution researchers against universalizing the experiences of women. Feminist theorists overwhelmingly reject knowledge that is grounded in totalizing theory, arguing instead that knowledge about the social world is neither provable nor objective. As feminist communication scholar Cindy Griffin notes, theory is a subjective compilation of explanations that are bound by the ideologies of the researcher and deeply influenced by the social milieu from which they emerged.

EVIDENCE

Evidence is the information currently available, at a given time, to support or disprove an assertion, notion, or theory. In the medical, educational, and social services realms, there has been an increasing emphasis on practices that are supported by evidence. Unfortunately, there is often confusion about what constitutes solid evidence, and many people use tenuous evidence to support their assertions and programs. Using weak evidence to inform decisions that affect many people's lives is irresponsible and could cause unnecessary harm while also wasting precious financial resources. Evidence from scientific studies is usually considered the most rigorous, but it is important to understand the different levels of evidence that can be created from scientific research. When complex theories are involved, there is often not enough current evidence to prove or disprove them, setting the stage for new scientific studies. With more data available now than at any time in history, it is important to discern the continuum between weak and strong evidence in order to make wise, evidence-based decisions and create effective programs to increase productivity, health, achievement, and well-being. In the following sections, this entry traces the increase in evidence-based practices over the past half-century and explores the nature of evidence itself. Among the questions addressed are what constitutes weak versus strong evidence for various claims, what types and levels of evidence constitute the

strongest support for scientific theories and hypotheses, which types of experimental designs are capable of producing the most reliable scientific evidence, and what sorts of instruments are most capable of assessing the value of purported evidence for the efficacy of various practices in, for example, education. The distinction is made between a lack of evidence to support a claim and the existence of evidence showing that a given product, program, or hypothesis is ineffective or harmful. The entry concludes with a discussion on the importance of evaluating evidence for the benefit of society and its institutions and for the sake of personal well-being.

Increased Emphasis on Scientific Evidence

The demands for evidence-based practices have increased since the mid-20th century for medicine, education, psychology practice, and in various other fields. In other words, administrators and practitioners are being held more accountable to demonstrate that their practices have a positive effect. For instance, the federal government now strongly encourages public schools to use instructional techniques that are supported by scientific evidence. Furthermore, schools across the United States must report on their students' progress each year, often measured by performance on statewide achievement tests. Unfortunately, many of the states' measures of achievements have not been adequately validated in peer-reviewed scientific journals, suggesting that achievement gains on state achievement tests may not be reliable and valid evidence of positive educational effects.

In the health care field, the pressure to provide evidence for the effectiveness of practices comes in part from the U.S. Food and Drug Administration (FDA) when it comes to medication. Medications are expected to demonstrate effectiveness through significant improvements in the health of a group of patients who receive the medication (the treatment group) compared with a group of patients on a wait-list or receiving a placebo (e.g., a sugar pill) over the course of a few weeks or months. Furthermore, the medication should not produce an inordinate frequency of dangerous side effects in the treatment group. In addition to the FDA, insurance companies may provide the impetus for using evidence-based practices by having a list of

approved procedures (or procedures they fund at a higher rate) that are supported by adequate scientific research.

Increasingly, private foundations and providers of federal grants emphasize evidence in determining what they will fund. Often, grant writers and investigators must make a clear and convincing argument that the components of the program they wish to initiate are informed by reputable theories and are supported by rigorous evidence. Furthermore, they must often explain how they will evaluate whether grant-funded programs will have the intended effect in the hospital, community, city, or state in which they will be applied. Although such program evaluation is not usually as rigorous as peer-reviewed scientific research (i.e., research reviewed by a group of expert scholars or scientists who do not know the author's identity), it is expected to be based on strong evidence.

Weak Evidence

Not all evidence is created equal. Many people assume that they have evidence for an assumption, folk theory, or pattern in life because they have seen it happen a few times in their own life or in the lives of people they know. For instance, let us say that Charlie feels compelled to wear a jester's hat every Sunday because his favorite football team has won most of their games when he wore the hat. He has even made self-deprecating remarks when he supposedly caused his team to lose by his not wearing the hat. Most people can tell that his wearing a jester's hat while he watches the game at a local bar has no effect on the outcome of a professional football contest, but Charlie swore by it until his team finally lost four games in a row. This type of superstitious thinking is an example of basing beliefs on flimsy evidence. It is also an example of what is known as *illusory correlation*, whereby two things seem related whereas other, more important factors (such as the injury list for the favorite football team and the records of the opposing teams) are ignored.

As a somewhat more insidious example of forming and conveying beliefs based on limited evidence, let us say that a dedicated teacher has seen three highly energetic African American boys from single-parent homes struggle academically,

and their performance only seemed to improve when later receiving special education classes or medication. If not rigorously and objectively analyzing the immediate and wider evidence, this teacher might assume that highly energetic young African American boys from single-parent homes who struggle academically are at a high risk for attention deficit hyperactivity disorder (ADHD) and only improve academically with special education or medication. Numerous research studies indicate, however, that many students do not improve academically in special education and that many students with ADHD continue to struggle academically even after receiving medication. There have also been studies indicating that African American boys are over-referred by teachers for ADHD-related concerns, even when girls and non-African American boys display similar levels of inattention, impulsivity, and hyperactivity during observations by an independent observer (a highly trained observer who has no personal connection to the people being observed). A keen clinical psychologist, school psychologist, or mental health consultant will be aware of this scientific evidence and help the team of educators analyze all existing data and then form *hypotheses*, which are clear and testable statements about what is likely causing the problem. Based on these hypotheses, the team would then develop interventions that strategically target the child's specific constellation of problems while also closely measuring the students' response to the interventions. Often, this leads to improved behavior and academic performance without special education or medication, but in other cases, the teacher's original impressions concerning the particular child may be proven correct. The important thing is that well-informed hypotheses are rigorously tested, so that professionals do not make major decisions that affect people's lives based on assumptions and limited evidence. Rather, rigorously testing hypotheses leads to richer evidence, making it possible for professionals to make decisions in light of stronger evidence.

The weakest level of evidence is that which relies either upon one's limited experience alone or upon the opinions of others who are basing their assertions on their own limited experience and knowledge. Scientists endeavor to avoid this by conducting studies involving many participants,

usually with whom they have no personal relationship, thereby promoting objectivity (seeing things clearly with much less bias). Furthermore, before scientists form hypotheses, they will usually diligently read the scientific literature on the topic, helping them to ground their views in relevant information and related theory rather than in the opinions that they and others might have expressed in person or in personal correspondence or popular media (e.g., blogs, newspapers, or magazines).

Levels of Scientific Evidence

Another generally weak form of evidence is that of relying heavily on percentages from surveys. Surveys, when they sample people properly, let us know what percentage of the population in a company, school, state, or nation view things in a certain way, but they tell us little about why. Furthermore, many surveys use what is called a *convenience sample* (e.g., the person at the mall asking you for "just 15 minutes" to fill out their survey on a clipboard or smartphone). The problem with convenience samples is that they usually do not represent the population of interest reliably. In the case of the mall survey, people with more time, people who are less assertive, or people who are very agreeable might be more likely to fill out the survey, providing skewed results (i.e., results that do not represent the whole group of people that the surveyor hopes to assess). Better survey studies use a random sample, such that everyone within the population being studied has an equal chance of being included in the study, yet survey studies are still problematic unless they address control variables, which are other factors that may affect results, such as the socioeconomic status (a mix of education level, wealth, and current occupation), gender, and ethnicity of the person filling out the survey.

Statistical correlations are an important form of evidence, but they are generally considered preliminary data. A *correlation* is the strength of the relationship between two variables. For instance, if there is a statistically significant correlation between how often parents read to their children (i.e., shared reading frequency) and how much those children achieve, this is interesting. However, this correlation could be illusory in that some

other variable related to both of these variables could explain the relationship. For instance, children who achieve more may have highly educated parents who model a fascination with learning more than most parents, which could lead to higher achievement. So, if we want to know whether shared reading frequency is causing improvements in achievement, we would seek higher levels of evidence. One might start by determining whether shared reading frequency predicts future achievement even when controlling for the effects of previous achievement, gender (girls often have slightly higher reading achievement), race/ethnicity, and family socioeconomic status. If these results are as predicted, one might proceed to conduct an even more rigorous study by randomly assigning students to either a treatment group that receives a parent-child shared reading intervention or a control group that is on a wait-list to receive the intervention later. If the treatment group improves significantly more than the control group, as demonstrated by statistical tests, we gain more confidence that parent-child shared reading causes an improvement in reading achievement. The evidence for the effectiveness of parent-child shared reading (or any other intervention) becomes even stronger when the findings are replicated in subsequent studies, especially when at least one of the subsequent studies is conducted by a research team that is independent of the developers of the intervention. This progression of research and correspondingly stronger evidence has been actualized in the realm of parent-child shared reading frequency. Even though scientists are rigorously trained to be objective, results replicated by another research team help to show that others can apply the methods successfully as well. Furthermore, the independent research team may have less interest in the intervention and thereby be less susceptible to introducing bias into the experiment, although scientists have ways of reducing bias, such as by having the data collected and entered by research assistants who are unaware of the hypotheses.

In the preceding example, families were randomly assigned to either a control group or an experimental group. Positive results from a randomized controlled trial (RCT) are usually considered the highest form of evidence in science, especially if the findings are replicated multiple

times with an adequate number of participants in each study. It is important that RCTs have enough participants because randomization disperses important unmeasured characteristics (e.g., motivation to improve, intelligence, and personality) between treatment and control groups increasingly evenly as the number of participants in a study increases. However, it is not always easy to use random assignment. For instance, people or organizations that agree to be in either the treatment or control group sometimes drop out of the study when they figure out that they are in the control group. That is, some people or organizations only feign agreement to participate in the RCT study in hopes of being assigned directly to the treatment group in order to receive an experimental treatment that they expected to be beneficial. Thus, random assignment to the treatment or control group is not always feasible or efficient.

The next highest form of applied experiment is the *quasi-experimental design*, in which people are recruited to join either the treatment or the control group, without random assignment. The people in the treatment and control groups may differ in some important way, but this can often be controlled for if effective pretest and posttest measures are employed. For instance, if one is studying how an intervention designed to treat symptoms of depression affects job performance, controlling for the prior skills, socioeconomic status, gender, mental health, and personalities of employees will help rule out important differences between the treatment and control groups. If the treatment group shows a statistically significant greater reduction in depression symptoms than the control group, researchers have found decent evidence that the treatment caused the improvement. However, only in an RCT with an adequate number of participants can we be sure that there is no difference between the groups (such as motivation to improve or some other unmeasured characteristic) that would explain improvement in response to a treatment. For this reason, positive evidence from quasi-experimental studies provides an impetus for following up with more rigorous experimental studies of the same treatment or program.

Although experimental and quasi-experimental designs help to create high levels of evidence for or against a hypothesis or proposition, they are relatively rarely employed. All too often programs are

evaluated in corporations, schools, states, and nations with very little rigorous evidence. For instance, countless programs are evaluated every year without any sort of control group. The biggest problem with not including a control group is that the design of the study makes it impossible to say whether or not the program or treatment caused any significant improvement that's been detected. Significant improvement detected within a study entailing solely a treatment group could be due to a host of other factors, such as people maturing (e.g., children developing cognitive skills as a function of natural child development), being more aware of their behavior when they know they are being assessed, or unmeasured interventions in other environments (e.g., a community-based support program positively affects employees' neighborhoods during the same time a work-based program/treatment is introduced). Conversely, when a program evaluation lacks a control group, the treatment group or program participants could make no improvement and the team could decide erroneously that the treatment or program did not work. This weak evidence could be used to decide to eliminate a potentially helpful program. For instance, let us say that a preschool and elementary school decide to promote parent-child shared reading in the home from preschool to first grade. After 3 years, the school administrators and educators analyze parent-child shared reading frequency data and are disappointed to find that the parents did not increase the amount of time they read with their children over the course of the 3 years. However, in a longitudinal study (a study that follows people over a long time) conducted by developmental scientists from Purdue University, Douglas Powell, Seung-Hee Son, Nancy File and John Mark Froiland found that many parents decrease their shared reading frequency (and other forms of home-based parent involvement) from preschool to first grade, when there is no special home literacy intervention in place. Thus, if the preschool and elementary school would have had a control group, they may have found the same thing, in which case the evidence would show that the treatment group remained the same while the control group showed a statistically significant decrease in reading with children at home. In light of the control groups' decreased performance, the

parent-child shared reading program might be considered a success because home literacy supports child development in various ways, but one would never know this without measuring the control group.

Longitudinal studies are not usually as rigorous as experimental and quasi-experimental studies, but they are an important improvement over studies that only assess people or groups once. In the preceding example of the study at Purdue, natural patterns among parents were discerned by observing them over a long period of time. That study also found that parents naturally increase their engagement in community-based activities (attending museums, zoos, public libraries, sporting events, and aquariums) with their children between preschool and first grade, which is important to know for anyone who wants to provide sound evidence that their program to increase community-based parent involvement has had a significant effect. Namely, program developers would need to demonstrate that their program had a positive effect above and beyond parents' natural development in this area. Longitudinal studies are also an improvement over studies with one wave of data because they establish what is called *temporal precedence*. Temporal precedence entails one variable occurring prior to another variable (e.g., high intrinsic motivation to help others and learn, predicting more success at work 2 years later). This helps to move toward establishing causation, but alone is not sufficient, which is why quasi-experimental or experimental studies are needed later. Longitudinal studies can help identify important patterns and help researchers, administrators, and policy makers to know whether the hypothesis is worthy of studying in a rigorous, sometimes risky, and often expensive experiment. In other words, it is important to gain as much knowledge and evidence as possible before conducting an experiment that may require more money and affect many people's lives in various ways.

The Importance of Assessment Tools or Outcomes as Contributors to Evidence

For any evidence involving outcomes to be considered sound, the measurement of the outcomes must be reliable and valid. A reliable measure

should yield similar results when given to the same person within a short time frame, when they are not receiving an intervention designed to change their performance. A reliable questionnaire should also have items that are internally consistent (i.e., measuring the same characteristic). Both of these forms of reliability reduce measurement error and lead to stronger evidence in support or refutation of a hypothesis. Reducing measurement error also makes it easier to detect a significant effect of a program, thereby reducing the chance that program evaluators will erroneously conclude that a program does not work. Reliability alone, however, does not make a measurement instrument trustworthy. Just because a measure keeps rating a workplace as having a positive climate does not mean that it is a valid instrument. For instance, if a significant number of workplaces rated as having a positive climate by an instrument end up having high turnover rates, unhappy workers, and low productivity, the validity of the scale may be low. The validity of a measure is often established with positive correlations between the instrument and other variables that should be significantly associated with the underlying construct. For instance, an intrinsic motivation (a love for what one does) test may be validated by intrinsic motivation scores being significantly positively correlated with achievement and happiness because both self-determination theory and previous research indicate that intrinsic motivation leads to greater happiness and achievement.

Unfortunately, people routinely use outcomes that may be unreliable or invalid. For instance, many schoolteachers use office referrals (students being required to visit the principal's office) as an outcome to measure the effects of a behavior intervention program. Reduced office referrals are supposedly a sign of better classroom behavior. But some teachers will take pride in the fact that they almost never refer a student to the office, and others will over-refer prior to the intervention but then refer less frequently once the program starts in order to please the principal. This leads to the measures being unreliable and invalid because students' behavior is not the sole determinant of whether they get an office referral or not. It would be better to use empirically validated behavior rating scales with

national norms (clear comparisons to the average boy or girl in the United States) or to use systematic observations by an independent observer (i.e., an observer who is neutral and is not biased toward the students, the program, administrators, or teachers).

Evidence in Support of Theory

In common parlance, the term *theory* is used very lightly, in terms of the evidence most people offer in support of their *theories*. Often, it would be more accurate for people to label their theories as conjecture, assumptions, hunches, or best guesses. Scientists are usually very careful about their use of the term *theory*. In fact, even a hypothesis is not usually formed until one has received years of advanced training in the area of inquiry, rigorously reviewed the scientific literature, and perhaps conducted other related scientific studies under the guidance of well-established scientists. Theories are used to guide the formation of many hypotheses that should be correct if the theory is accurate. Each hypothesis must be tested and replicated in rigorous scientific studies before the theory has adequate evidence. All the aforementioned types of scientific evidence can be used to support the development of a theory, but generally the theory will not be recognized until it has numerous longitudinal and experimental studies to support it. Also, theories must be testable, which makes them capable of being refuted, confirmed, or revised in light of evidence. When one sets forth a theory that cannot possibly be tested, scientists will generally point out that it is not a scientific theory or not a theory at all.

It is important to point out that only scientific studies that are published in peer-reviewed scientific journals are generally considered as evidence or counterevidence related to a theory. Editors of peer-reviewed scientific journals typically send *blind copies* (copies that do not identify the names of the authors) of the manuscripts submitted to three or more established scientists who are either experts in related content or the methods addressed in the study. When the editor chooses to reject a manuscript, it is usually due to major weaknesses in the measures, methods, or review of the scientific literature. This helps to

prevent evidence that is not sound from entering the scientific body of literature.

Many infomercials, product websites, and flyers claim that their product leads to greater vitality, fitness, health, success, and so forth. However, these commercials often rely heavily on testimonials, including paid testimonials. Although testimonials can be interesting and even quite compelling, the fact is that most consumers do not really need to know if the product works well for one or two people that appear in the advertisement; they need to know whether there is evidence that it works for most people and how well it usually works. They may even want to know if it usually works well for people of similar backgrounds and ages. This is where scientific studies help to provide the type of evidence consumers truly want. Some product developers avoid the scrutiny of peer-reviewed journals because they fear that the lack of a significant positive effect would be discovered. In other words, they fear that rigorous scientific studies would demonstrate the inefficacy of their products. Most of the *evidence* that many advertisements provide would not be considered as sound evidence in support of a hypothesis, treatment, program, or theory. Advertisers of some products go even further to avoid evidence by simply showing imaginary people (actors playing characters) having fun, getting dates, or being very successful while using a product. In doing this, they are trying to bypass reasoning about evidence altogether, hoping that consumers will simply identify with the characters and want the rewards that are putatively associated with the characters and the product.

Lack of Evidence Versus Negative Evidence

It is very important to distinguish between a lack of evidence to support a product, program, or hypothesis and the existence of evidence showing that product, program, or hypothesis is ineffective or harmful. For instance, on the basis of a plethora of rigorous scientific studies over the course of decades, the U.S. Surgeon General has confidently declared that smoking cigarettes causes lung cancer, cardiovascular disease, and pulmonary disease. There is also ample research to indicate that Drug Abuse Resistance

Education (DARE) is not an effective prevention program and that there are many other, less popular, drug abuse prevention programs that are effective. In both of these cases, strong forms of evidence indicate that cigarettes and DARE are not worth the investment of financial resources.

In contrast, there are many programs, products, and interventions being used across the world that simply have not been subjected to rigorous scientific study (e.g., longitudinal, quasi-experimental, and experimental studies using reliable and valid measures of outcomes) and then submitted to peer-reviewed scientific journals. Likewise, there are many assumptions, beliefs, and assertions that have not been rigorously tested. It would be misleading to say that those untested beliefs and products are no good or harmful. One can only say that they do not have strong evidence either supporting them or disproving them. In some cases, products and programs have not been tested because the developer is avoiding peer review, but in many cases, they have not been tested because of a lack of understanding of the benefit of testing them and a lack of understanding of the levels of scientific evidence. For example, as mentioned before, many administrators and practitioners do not realize that without employing a control group, there is no way of knowing whether a program or treatment works for most people. There are also some beliefs and assertions that are frankly not testable at this time but may be testable in the future as technology and science advance. It is important to realize that beliefs that are not supported by high levels of scientific evidence at this time may in fact prove to be powerfully correct at some point in the future. For instance, current science is unable to test metaphysical and spiritual claims, with the exception of repeatedly finding that people who are active in their faith are generally less depressed and recover more quickly from diseases, on average. Therefore, it is important to recognize the limits of science in gathering certain types of evidence, when discussing the highest levels and most convincing forms of evidence.

In conclusion, the increased emphasis on evidence in modern society suggests that those who can gather and analyze evidence effectively are likely to become increasingly valuable to corporations,

universities, schools, and communities. However, analyzing evidence well also has personal benefits, such as making wiser decisions about investments in products or programs. Knowing and identifying the types of weak evidence that many people rely on can prevent one from being misguided by unfounded assertions in the realm of politics, advertisements, or proposed community projects. Furthermore, understanding the levels of scientific evidence can help consumers and leaders better evaluate the existing evidence while helping program evaluators in various domains of life to conduct more rigorous evaluations that produce stronger evidence in support or in refutation of hypotheses.

EVOLUTIONARY PSYCHOLOGY

Evolutionary psychology involves understanding the human mind and behavior from an evolutionary perspective, starting with Charles Darwin's theory of natural selection and including advances in theory and data over the last 160 years. The basic tenet of evolutionary psychology is that the human mind has been prepared by natural selection, operating over geological time, for life in a human group. Evolutionary psychology recognizes that humans are social animals and that much of our evolved psychology concerns how to cooperate and compete with our fellow *Homo sapiens*. Evolutionary psychology as a formal academic discipline is relatively young, dating back only to the last decades of the 20th century. Its roots, however, can be traced back to Darwin's 1859 seminal book, *On the Origins of the Species*, where he wrote, "In the distant future . . . psychology will be based on a new foundation, that of the necessary acquirement of each mental power and capacity by gradation" (p. 488).

Central to any evolutionary theory is the concept of *adaptation*, reliably inherited features that helped organisms survive and reproduce. An

evolutionary perspective on human thought and behavior assumes that not only has the human body been adapted through evolution for survival (e.g., the opposable thumb critical for fine-motor actions necessary in tool use; the digestive system adapted to an omnivore diet) but so has the human mind and behavior. Moreover, adaptations are found across the life span—not only in adults who do the all-critical reproduction but also in infants and children, serving to keep them alive through a perilous time in life and to prepare them for adulthood.

Although an evolutionary perspective can be applied to any areas of human behavior, it is primarily concerned with four general topics: *survival*, including food preferences and predator/prey relations; *reproduction*, including sexual attraction and mate selection; *parenting*; and *social relations*, including learning how to compete and cooperate with the fellow humans, reciprocity, in-group/out-group relations, and status striving. The following sections examine some of the assumptions and principles of evolutionary psychology and then provide examples of human adaptations related to survival, reproduction, parenting, and social relations.

Assumptions and Principles of Evolutionary Psychology

Darwin's Theory of Natural and Sexual Selection

Evolutionary psychology takes as a starting point Charles Darwin's theory of evolution by *natural selection*. Natural selection has four general components. First, within a species, more individuals are born in a generation than will survive. Second, there is variation in form or function among members of a generation. Third, this variation is inheritable. And finally, features that result in individuals surviving and reproducing tend to be selected as a result of the interaction between the individual and the environment. Natural selection is not forward looking or necessarily is the *best* solution to a problem but rather works with what is already available, adapts individuals to their local environment and not to a future one, and is economical so that more individuals with a particular feature will survive and reproduce than

those without it. Darwin also emphasized that selection operated at the individual level, not at the level of the group or species. In the early 20th century, Darwin's theory was integrated with the genetic theory of mathematician, biologist, and Augustinian friar Gregor Mendel (1822–1884), producing what has been called *neo-Darwinism*, or the *modern synthesis*.

In addition to natural selection, Darwin noted that some traits evolved simply because members of one sex found them attractive in the opposite sex, even if they might have been a handicap for the sex that possessed them. Darwin referred to this as *sexual selection*. Consider the peacock's tail. Males with long and beautiful tails are favored by peahens, even though the large tails make the males more susceptible to predation. Yet, large and beautiful tails are honest signs of health ("I must be healthy if I can carry around this tail and still be alive"), a signal to females that such males will likely provide good genes for their babies.

Evolved Psychological Mechanisms

Perhaps the central concept in evolutionary psychology is that of *evolved psychological mechanisms*. These are information-processing mechanisms (i.e., brain-based ways of encoding, processing, and storing information) that underlie thought and behavior and are the *missing link* in evolutionary explication. Early theorists proposed that these mechanisms are *domain specific*, in that they were shaped by natural selection to solve specific recurrent problems faced by our ancestors (e.g., identifying social cheaters; ideal characteristics in a potential mate), analogous to different organ systems in the body (e.g., the lungs evolved for respiration, the heart for pumping blood). These evolved mechanisms should not be viewed as being expressed in exactly the same way in all individuals in all circumstances but rather viewed as predispositions or biases in terms of how certain classes of information should be processed and are then shaped by experience to produce (usually) adaptive outcomes. Thus, evolved psychological mechanisms display a high degree of *plasticity* (the ability to change), permitting individuals to adapt to a wide range of environments. Contemporary theory postulates that humans also evolved some

domain-general information-processing mechanisms, permitting individuals to deal with novelty.

As an example of evolved plasticity, consider recent findings from *life history theory*. Life history theory is a mid-level evolutionary theory concerned with decisions animals make in allocating time and energy to various aspects of their development. With respect to humans, children growing up in environments that are harsh (low income, lack of resources) and unpredictable (frequent change of residence, unreliable and changing social relations) modify their development in anticipation of having similar environments as adults, developing a *fast life history strategy*. They thus take an opportunistic perspective, reaching puberty earlier, engaging in more risky behavior, and becoming sexually active earlier with more partners in comparison with those who, as children, grew up in less harsh and predictable environments, and who generally take a more futuristic approach to life, developing a *slow life history strategy*. Although the life course of children following a fast life history strategy may be seen as maladaptive from a broader societal perspective, it is well adapted to the difficult life circumstances such children can anticipate in adulthood.

Environment of Evolutionary Adaptedness

Evolutionary psychologists refer to the time and ecology when an adaptation arose or became established as the *environment of evolutionary adaptedness*. Roughly speaking, it refers to the environment to which a species is adapted. Humans are mammals and thus share a long evolutionary history with all other mammals, along with adaptations. Humans last shared a common ancestor with chimpanzees and bonobos between 5 and 7 million years ago (mya), with fossil evidence of the first member of the human family (*Homo habilis*) dating back about 2.5 mya, with anatomically modern *Homo sapiens* appearing in Africa as early as 300,000 years ago. With respect to unique human psychological adaptations, most evolutionary psychologists focus on the last 300,000 years, when our ancestors made their living as nomadic hunter-gatherers on the savannas of Africa. Fossil and archeological evidence, plus information about how modern hunter-gatherers

live, give us an idea of what the life of our ancestors might have been like.

Our ancestors likely lived in small, nomadic groups of between 30 and 100 people, interacting occasionally with other groups, trading mates and goods. They obtained nutrition mainly by gathering (mostly the work of women), hunting (mostly the work of men), and scavenging. Females likely reached puberty and had their first births in their late teens or early 20s, nursed infants for about 3 years, and gave birth every 4 to 5 years. Child-care was done primarily by mothers with the help of other women in the group, with fathers providing protection and nutrition for their mates and children. Early humans were probably marginally monogamous/polygamous, with some men having several *wives*, although most men likely had a single wife, with some men having no access to women. The physical environment of Africa, and later of Europe and Asia, was highly variable over the past 300,000 years, meaning ancient humans had to be able to adapt to substantial changes in climate and habitat. *Homo sapiens* developed agriculture and began to live a sedentary lifestyle about 10,000 years ago. Since that time, the pace of cultural evolution has outstripped that of biological evolution, and because of this, many adaptations that evolved in ancient environments and are inherited by contemporary humans are sometimes mismatched to modern environments. For example, humans' preference for sweet and fatty foods made good sense when people did not know where their next meal was coming from but may be maladaptive for people in industrialized societies living with fast-food restaurants and grocery stores. In addition, just because an adaptation evolved in the environment of evolutionary adaptiveness or is based in our biology does not make it *good*, *right*, or *justified*, nor does it mean that it is inevitable. This is the *naturalistic fallacy*, and human behavior evolved to be sufficiently plastic (changeable) so that biology need not be destiny.

Survival

Knowing What to Eat and What Not to Eat

Humans are omnivores, eating fruits, vegetables, and meat, and like all omnivores must learn what is okay to eat and what potential foods must

be avoided. Humans' evolved preference for sweet and fatty foods was mentioned earlier. Such taste cues are signals of foods high in calories and thus nutrition. Other tastes and odors, being cues of potentially toxic substances, seem to result in avoidance, with pregnant women being especially sensitive to certain tastes and smells. For example, many women in the early stages of pregnancy develop aversions to certain types of foods, including bitter-tasting vegetables (for instance, broccoli), meat (especially raw or undercooked meat), and alcohol, all substances that, particularly in ancient environments, could interfere with the development of the fetus they are carrying. Infants acquire some early taste preferences based on the diets of their mothers, both while still in utero through the placenta and after birth through breast milk. For example, in research where mothers ate anise-flavored food several weeks before giving birth, their babies showed a preference for anise-flavored milk after birth, relative to nonexposed infants. Humans' potent social learning abilities also result in children learning to eat what their parents and other adults in the group eat, making it likely they will develop food preferences similar to those of their parents.

Nonetheless, even when adopting the same eating habits as more experienced others, food sometimes makes us sick. Given that there is often an extended delay between consuming food and experiencing sickness, how do people know what it was that made them sick and avoid it in the future? Humans and other omnivores, such as rats, seem prepared to associate sickness with novel foods they have eaten. Such *prepared learning* is illustrated in experiments with rats in which they drank artificially sweetened water (a novelty for them) and were subsequently exposed to low levels of radiation that made them sick hours after consuming the water. After recovering, the rats avoided the novel water when given an option. In this respect, humans are no different, and this has sometimes been referred to the *sauce béarnaise effect*, reflecting the belated nausea that spoiled béarnaise sauce can have and people's subsequent aversion to it.

Developing Fear of Predators

For our ancestors, staying alive meant avoiding being eaten by carnivores or otherwise killed by

dangerous animals. Snakes remain the vertebrate causing most human death in the world today, and they were surely a threat to our ancestors. Fear of snakes seems to be universal, with many individual differences, although such fear seems not to be innate but rather easily acquired when infants and young children watch someone respond fearfully to snakes. For example, in one research project, infants and toddlers viewed short videos of snakes and other animals while they listened either to a pleasant or a fearful voice. The children looked significantly longer at the snakes when they were paired with a fearful voice than with a pleasant one. There were no differences in their attention when pleasant and fearful voices were paired with other potentially dangerous animals such as an elephant or hippopotamus. Apparently, snakes' sinusoidal movement, different from the movement of mammals, attracted infants' attention and became an associative cue in children's developing a fear of this prehistorically dangerous class of animal. Other research has similarly shown that monkeys have no innate fear of snakes, but, like human children, can easily acquire such fear by watching another monkey respond fearfully to snakes. They do not develop fear responses when they watch another monkey respond fearfully to a rabbit or a flower.

Reproduction

Parental Investment Theory

The essence of evolutionary theory is reproduction, passing one's genes to the next generation. In humans and most animals, reproduction is done sexually. Although at one level males and females have the same goal (having offspring that grow up to be reproductive adults themselves), the self-interests of the two sexes are not identical. This is best understood from the perspective of *parental investment theory* as initially articulated by Robert Trivers in 1972.

The principal concept of parental investment theory is that there is a conflict for both males and females in how much time, effort, and resources to invest in mating versus parenting. In most mammals, including humans, there is greater obligatory investment in parenting for females than for males. Greater female investment begins with the

size of gametes (eggs being substantially larger than sperm), followed by internal fertilization and gestation, and nursing, which, until the modern era, was the only source of nutrition for young infants. Females in all cultures also spend more time in childcare than males do. According to the theory, this differential investment in parenting between the sexes results in the sex that invests less in parenting (usually males) being more willing to engage in sex and being more competitive with members of the same sex for access to members of the opposite sex. This pattern generally reflects sex differences in behavior in most mammals, including humans.

For example, women are more hesitant to consent to sex and are less desirous of having multiple sex partners than men are. A single sex act can result in 9 months of pregnancy for a woman and several more years when she is the sole source of nutrition for her baby. A man's potential contribution can be as little as his sperm and the time it takes to copulate. Many men do commit to women and their children, however, and they are most apt to do so when such commitment is necessary for the survival or social success of their children, and when it is necessary to attract a high-quality mate (commitment is what women want).

The higher rate of aggression, including homicide, for adolescent and young adult males than for females reflects males' greater competition for social status, which women value in men. Although most women will find a mate, even if a less-than-desirable one, some men in some societies can be shut out of mating entirely, making it worth their while to engage in reckless and often potentially deadly actions.

Sex Differences in the Ideal Mate

In most cultures, men and women want the same thing in a mate: someone who is kind and loving, healthy, and compatible in interests and personality. But there are typical cross-national, pan-cultural differences in the features that males and females desire in an ideal mate, and these can be explained (and predicted) by evolutionary theory. For example, men more than women value attractiveness and youth in a potential mate. The reason for this seems to be that both

attractiveness and youth are associated with health and a woman's *reproductive value*—how many children she can have in the future. For instance, degree of facial symmetry (the extent to which the left and right sides of the face are similar) is a major contributor to people's ratings of attractiveness and a reflection of low levels of perturbed development and thus health. Moreover, men in most societies find women with an hourglass shape (a waist-to-hip ratio of about 0.7) the most attractive, and this shape has been found to be related to fertility in cultures that do not use hormonal contraceptives. In contrast, women more than men in most cultures value high social status and access to resources, such as food and money, as more important in a potential mate. This reflects the ability of a man to invest in her and her offspring.

Jealousy

Infidelity is a problem in any relationship, and becoming jealous of a potential competitor for one's partner's attention can be adaptive, in that it can promote behavior aimed to enhance the relationship (being more attentive to one's partner) or behavior aimed to punish via aggression toward the partner or the potential competitor.

Jealousy comes in (at least) two forms—sexual and emotional—and men and women tend to respond differently to the two types. Sexual jealousy involves concerns that one's partner is having sex with someone else, whereas emotional jealousy involves concerns that one's partner is becoming emotionally involved (without having sex) with someone else. Both men and women are disturbed by both types of jealousy, but both verbal reports and physiological measures (blood pressure, galvanic skin response) show that men are more bothered by a partner's sexual infidelity and women more bothered by a partner's emotional infidelity. Men's greater distress with a partner's possible sexual infidelity is explained by *paternity uncertainty*. Prior to the advent of genetic testing, a man could never be 100% certain that he is the genetic father of a child born to his partner, and if his partner were having sex with another man, this can result in *cuckoldry*, a domestic father raising a genetically unrelated

child. In contrast, a woman always knows that a baby is hers, so the consequences of sexual infidelity are not as great for a woman. (She's not about to unknowingly raise another woman's child.) However, if her partner becomes emotionally involved with another woman, this could lead to him abandoning her and her children for another woman, and this, traditionally, has been a greater risk for women.

Parenting

Investing in Infants

Infant and child mortality rates for our ancestors were likely about 50%. Ancestral women thus had to carefully evaluate the likelihood of any child surviving to adulthood and invest in each child accordingly. Women who devoted too many resources to a sickly infant, for example, jeopardized the health and survival of any current children she had as well as any future children she might have. There are a variety of factors that ancestral (and many modern) women must evaluate to determine how much (or how little) to invest in an infant. Perhaps most important is a child's health. In traditional cultures, sickly infants are apt to receive less investment and are more apt to be abandoned than healthier infants. For instance, if twins are born and the mother lacks the resources to raise both, the weaker of the two is likely to be abandoned. Younger children are more likely to be abandoned or given fewer resources than older children because the older children have already survived to a greater age and thus are more likely to reach adulthood than younger children. Younger women are more likely to abandon an infant than older women because they will have more subsequent opportunities to become pregnant and have children, and women with greater social support (a mate, family) are more likely to invest heavily in an infant than women with less social support. Although we may like to believe that women (and men) love all their children equally and will invest whatever is needed for their survival, the truth for ancestral women (and to a lesser extent men) is that they had to be discriminating in how much to invest in any child, and it was such discriminating women who became our foremothers.

Adaptations of Infants to Garner Adult Attention

Infants, however, are not passive recipients of their parents' attention but have evolved a set of psychological *weapons* to obtain attention from adults to increase their chance of survival. For instance, infants are attentive to biological motion, are especially attentive to faces, and are responsive to adults' facial expressions, all of which encourage adults' caregiving. Infants' large heads, eyes, and other features of babyhood promote positive feelings and caregiving in adults, particularly in women and especially for a woman's own infant, again increasing the likelihood of mother–infant attachment and thus infant survival. Recent research has also shown that infants as young as 9 months of age will show *jealousy protest* when their mothers pay attention to another infant in contrast to when they attend to an inanimate object such as a book. Another infant is a potential social rival, and jealousy protest may serve to decrease the chance of an infant being displaced by a competitor.

Social Relations

Humans Are a Hypersocial Species

Humans are a highly social species but so are chimpanzees, wildebeests, wolves, and baboons, among many others. But humans' sociality is extreme—we are *hypersocial*, displaying a remarkable ability to cooperate with others to achieve tasks that a single (or even a handful) of people could not accomplish. Human cooperation extends beyond family and friends, often involving large groups of people, some of whom might not be known well or at all. Human sociality involves notions of morality, often helping others and treating others fairly at some expense to oneself, which is found in all cultures (although the specific moral prescriptions can differ substantially among societies). Darwin had difficulty explaining humans' sense of morality and seeming acts of altruism and suggested that human morality may be an exception to his rule that natural selection only operates on the level of the individual and indeed may, in this case, operate on the level of the group.

The nature of human altruism and *Homo sapiens'* hypersociality has been a contentious one ever since Darwin. One current account, *multi-level selection theory*, holds that natural selection operates at a variety of levels, the group being one of them. Specifically, groups of individuals showing high levels of cooperation function more efficiently than less cooperative groups and are more apt to survive and thrive. From this perspective, selfish individuals are likely to outcompete altruistic individuals within a group, but altruistic and cooperative groups are likely to outcompete selfish groups.

Humans' tendencies toward cooperation can be seen early in development. Although 3-year-old children are not known for their tendency to share and treat others fairly, when they work together to obtain some reward, they tend to distribute the spoils of their efforts evenly. Highly social chimpanzees do not do this (nor do human 2-year-olds), and as a result, collaborative efforts between chimpanzees quickly decline when one member of a pair consistently takes the larger portion of the rewards.

This is not to say that humans always cooperate with one another and are always considerate of others. Both selfishness and cooperation characterize *Homo sapiens*, and the social adaptations necessary for altruism and high levels of collaboration evolved from evolutionary adaptations that humans share with other primates. Along these lines, in order to understand human sociality, it is necessary to contrast it with that of our close genetic relatives, chimpanzees and bonobos, who are the best models we have for what our last common ancestor with these animals may have been like. Extending this argument, Michael Tomasello has further proposed that it is necessary to focus on how the development of great ape sociality has been transformed into the development of human sociality.

Adapted to Social Life

Much like other social animals, humans have a strong tendency to affiliate with other group members and as a result tend to show favoritism toward in-group members and fear of/or hostility toward out-group members. Experiments have shown that very little is needed for people to identify with a group and show favoritism toward that group.

Simply being assigned different colored T-shirts can result in group identification, with in-group members (people wearing the same color T-shirts) being viewed more positively and receiving more benefits than out-group members (people wearing different color T-shirts). Moreover, such in-group/out-group distinctions based on this *minimal groups paradigm* is observed even among preschool children. People, again beginning in early childhood, tend to pay attention to and adopt social norms, often penalizing people who break such norms.

Humans, like other social animals, are also status seekers. Individuals who have higher standing in the group often have access to more resources, which can translate into enhanced mating opportunities and benefits to themselves and their offspring.

Nothing in Psychology Makes Sense Except in the Light of Evolution

An evolutionary perspective provides a meaningful context in which to make sense of human cognition and behavior. An evolutionary perspective does not deny the role of experience or culture in shaping human behavior. Humans are, and always have been, a cultural species, and they have evolved adaptations for living in cultural groups. Nor does an evolutionary perspective imply *genetic determinism*, the idea that genes determine behavior. The ability to adapt to changing environments (plasticity) is an evolved feature of *Homo sapiens*. An evolutionary perspective on human psychology serves to organize known facts economically; provides guidance to important domains of human functioning, including those associated with modern culture such as psychopathology and formal education; leads to new predictions about human behavior; unifies psychology with the other life sciences (biology, medicine); and can serve as a *metatheory*—a common set of broad, overarching assumptions and principles—for other areas of psychology.

EXPERIMENT, THEORY OF

Experiments to understand and improve agriculture and animal husbandry must be as old as the history of humankind once we had ceased to be exclusively hunter-gatherers. Yet even the great advances in these areas in the late 18th century were achieved without any general theory of experiments. The same holds for the experiments of Renaissance scientists such as Galileo, of many 18th- and 19th-century chemists and of 19th-century experiments in science and engineering. These often took place in laboratories under carefully controlled conditions; typically, only one factor was varied at a time. Toward the end of the 19th century, in North America, Europe and its colonies and dependencies, and Japan, there was a marked development of research stations devoted to agricultural experimentation. However, it was not until the second decade of the 20th century that a theory emerged, leading to efficient experiments with many factors that allowed for the haphazard fluctuations that come with the measurement of natural systems. The first systematic understanding and discussion of this theory seems largely to have been due to Sir Ronald Fisher, indeed working at an agricultural research station. His contributions to the theory of design of experiments and their analysis are the subject of the next section. Thereafter, this entry traces the development of these ideas as the theory extended to cover technological and computer experiments. In what follows, the topics are introduced in historical order.

Sir Ronald Fisher and Agricultural Experiments

The Rothamsted Experimental Station was started in 1843 by John Bennet Lawes on his estate, Rothamsted Manor, in Hertfordshire, England. Lawes had founded one of the first artificial fertilizer manufactories. His initial purpose was to investigate the impact of inorganic and organic fertilizers on crop yield, at a time when it was still common belief that organic chemicals differed in the presence of a *vital force* from those that were inorganic (the synthesis of urea dates from 1828). Lawes launched a series of long-term field experiments, some of which continue to this day. Over

the next half-century, Lawes and his scientific adviser Joseph Gilbert established the foundations of modern scientific agriculture and the principles of crop nutrition.

In 1919, the young Ronald Fisher (he was born in 1890) was employed at Rothamsted to investigate the possibility of analyzing the data resulting from the station's crop and grasslands experiments. This experience led him to the first systematic formulation of a theory of experimental design. Because of this background, much of the nomenclature for the subject comes from that of the agricultural field trial.

The central problem in the theory of the design of experiments is which treatments to apply to which units. The units may be plots in a field, patients, batches of raw material, and so forth. The treatments are procedures under the control of the experimenter that are to be applied to individual units. In agricultural experiments, they might be the amounts per square meter of nitrogen, phosphorus, and potassium (NPK), perhaps together with numbers and times of application. In a clinical trial, the treatment is often the dose of a particular drug, administered in a particular way, such as by tablet or injection. In cereal experiments, the response is usually the yield of grain, although secondary responses, such as the length of wheat stalks, may be important in identifying varieties that will not be damaged by storms, a form of robustness discussed later under the industrial contributions of Genichi Taguchi. In a clinical trial, the response might be reduction in blood pressure, or in number of malarial parasites, following treatment.

Fisher's contributions can be summarized under four headings.

1. *Randomization and Systematic Error.* The treatments need to be allocated to the units in such a way as to avoid biases. If a particular treatment is allocated to an especially favorable set of units, the comparisons with other treatments will be biased. Widespread empirical evidence shows that haphazard allocation by experimenters can lead to such biases and is almost always unsatisfactory. An objective randomization procedure is necessary for the establishment of results that can be confidently extended to other, seemingly similar, situations. This is particularly true, for example, in clinical trials, where the

effects to be measured may be small and subjective reactions of patients and assessors may obtrude.

2. *Control of variability.* If there is appreciable variability between units, accuracy of comparisons between treatments will be improved if they can be made within sets of units (*blocks*) with similar properties. The analysis seeks to estimate the differences in treatment effect accounting for variation between blocks, making sharper comparisons possible. The simplest case is when all treatments are allocated to each block. In agricultural field trials, the blocks will be neighboring parts of a field, although the shape and extent of the block may be determined by the geology and agricultural history of the field. The allocations of treatments within blocks should be randomized, partly to avoid any systematic bias due to unexpected inhomogeneity between plots within blocks.

3. *Independent replication.* The effect of treatments has to be assessed against the intrinsic variation in the response to the same treatment applied under identical conditions to similar units. This can be achieved by repeating some treatments within blocks and, at the cost of further assumptions, by the use of models in analyzing the data. An important assumption is that of unit-treatment additivity, stressed by Jerzy Neyman. Of course, modeling assumptions can and should be checked during the analysis of data.

4. *Factorial designs.* The efficiency of an experiment can be greatly improved by asking several questions at once. The most powerful example is the factorial experiment. To continue with the example of field trials, suppose that interest is in the effects of levels of NPK, which are all to be applied at a high and a low level. The exact definition of these levels will depend on previous experiments and background knowledge. In the experiment, there are eight distinct combinations of treatment levels. When these eight levels are all repeated the same number of times, the resulting design is *orthogonal*; under simple assumptions, it is possible to estimate the effect of each treatment as if the others were not there; estimates of all three treatment effects are obtained which are just as precise as if each of the other two factors had been held constant—a *one-at-a-time* design.

The second powerful feature of the factorial experiment is that it allows detection of interactions which arise if the effect of one factor depends on the level of one or more of the remaining factors. Such important effects occur frequently in experimental work. Crucially, for the theory of design, they cannot be detected from experiments in which only one factor is varied at a time.

Fisher's main contribution to the analysis of experiments is the collection of techniques known as the *analysis of variance*. This was developed at the same time as his theoretical and practical work on experimental design. It comes from the use of least squares to fit a series of models of increasing complexity to data. Although the derivation of least squares goes back to Carl Friedrich Gauss and Adrien Marie Legendre in the first decade of the 19th century, Fisher emphasized the division of the total sum of squares of the observations into components corresponding to estimated treatment effects, to differences between blocks, and to random error. The assumption of normally distributed random errors leads to the distributions of the statistics for testing the values of the estimated treatment effects. For orthogonal designs, he provided straightforward calculation formulae, which remain widely taught and used, and geometrical interpretations in terms of Pythagoras's theorem. He also argued that interpretation of the calculations was little affected by small departures from the assumption of normality.

This approach is based on modeling. Another approach, which does not require a model, reuses the existing data from the randomized experiment. Given a statistic calculated from the data, its significance can be obtained by repeatedly re-randomizing the observed responses to the design and calculating the value of the statistic for each randomization. The significance of the observed statistic is its position in the ordered values of the statistics generated by this series of re-randomizations. Although the approach is model free, the power of the randomization test will depend on the choice of statistic. The method depends on the validity of the assumption of additivity of the treatment effect to that of the unit, where the unit effect is the baseline that could be expected in the absence of any treatment. If this assumption does not hold, it may often be achieved by data transformation.

For example, a logarithmic transformation renders a multiplicative effect additive.

Theoretical results, such as the Neyman–Pearson lemma, indicate the statistic for the most powerful test, under the conditions of a specific model. Quick graphical checks of models are rendered easier to interpret by the balanced treatment allocations of designed experiments. For example, in a factorial experiment, plotting the responses, or their means, against the levels of each of the factors in turn often indicates whether an interaction is present; in the absence of interaction the results for the differing treatments differ by the same amount, within experimental error, whatever the level of the plotting factor. Changes in variance with the level of the factor are an indication of heteroscedasticity, which can often be removed by transformation of the data. These suggestions for model enhancement are then followed by formal model fitting, parameter estimation, and hypothesis testing.

Perhaps the most important aspect of Fisher's work on the design of experiments is the emphasis on randomization to avoid sources of potential bias. But well-designed experiments, following his precepts, are frequently also easy to analyze. As a consequence of balance and orthogonality, a few simple graphics often reveal the important aspects of the effects of treatments. Haphazard experiments, apart from their inefficiency and susceptibility to bias, may lead to poorly identified treatment effects. Even if an effect is evident, the lack of orthogonality may make it impossible to ascribe the effect to changes in specific factors.

Clinical Trials

Clinical trials are experiments to determine treatments for patients. Although they are very different from agricultural trials, the theory described earlier makes a vital contribution, but with a rather different emphasis. In Phase III of such trials, a few treatments are compared. Often just two, a standard treatment and a new one that may offer medical advantages or may be not worse than the standard but cheaper, or preferable in some other way, for example, the absence of side effects. In such experiments, the effects are likely to be small compared with the variation in response

in the population of patients. Random allocation of treatments to patients is important, perhaps after patients have been stratified, for example, by gender or initial disease severity. The randomization needs to be blinded to the physician determining treatment, as well as to the patient. In addition, it needs to be blinded to medical personnel who are involved in the care of the patients and the assessment of their subjective feelings of well-being. Such *double blinding* is widely considered necessary by regulatory agencies to help ensure the objectivity of the results of the trial.

Patients can be recruited for a trial and all be randomized to treatment before the trial starts. Or they can be recruited sequentially and again randomized to treatment. Particularly in sequential trials, the randomization needs to achieve some balance over the prognostic factors with which the patients present. Randomization is usually over a few factors. It may turn out, after the experiment, that there are some imbalances in allocation, for which a specific regression method, the analysis of covariance, can be used to make adjustment.

Industrial Experiments: George Box and the Response Surface

One branch of the theory of design for industrial experiments was developed, after the Second World War, by George Box and colleagues, initially at Imperial Chemical Industries in Manchester, England. In the kind of experiments they encountered, the response was a smoothly varying function of continuous factors, such as temperature, time, chemical concentration, or stirring speed. In some experiments, the aim was to find the maximum over the factor values of such responses as the yield of product. In others, a model for the response was required over a known region: Economic modeling would then establish the best conditions of operation as prices of energy and the input chemicals varied. There is less emphasis on qualitative factors than in agricultural experiments. Furthermore, the units are often more uniform so that replication is of lesser importance in industrial experiments.

Typically, second-order polynomials provide satisfactory models. To fit such models the experiment needs to provide observations at, at least,

three levels of each factor. However, three-level factorials with each factor at a low, intermediate, and high level may rapidly become too large. For three factors, the design requires observations to be taken at 27 factor combinations, while the full model contains only 10 parameters (a constant, the linear and quadratic effects of each factor, and the three two-factor interactions). For four factors, there are 81 factor combinations to estimate a model with 15 parameters. Such designs, because of their large size, may waste resources. The parameter estimates are often more precise than are needed for determining important effects; part of the resources might better be spent on other experimental programs.

Box's contribution to the theory was to focus on the purpose of the design, in his case estimation of the response, rather than on such properties of the design itself as orthogonality. This led to the idea of rotatability, in which designs were found for which the variance of the estimated response increased away from the center of the design in a way that did not depend on the direction. The variance was thus spherically symmetrical. Designs providing such a variance function for a second-order model included two-level factorials augmented by observations taken at the center of the design region and *star points*; these are design conditions in which the experimental settings for all except one factor are held at the central value. The scaling of the design region and the number of center points are determined by the importance of the variance of the response relative to concerns about bias from an inadequate model.

These designs are much smaller than three-level factorials. For three factors, the response surface design contains 17 trials, if three center points are included, compared with 27 for the factorial design. For four factors, the numbers are 27 and 81, with the ratio continuing to decrease as the number of factors increases. The designs are widely used in the process industries, together with two-level factorials and their fractions. The fractional factorial designs allow estimation of main effects and low-order interactions. One application is to provide relatively small response surface designs as the number of factors increases, through replacement of the full two-level factorial by a fractional design.

A disadvantage of such designs in some circumstances is that they are *exact* designs; they give a

specific number of observations at combinatorial combinations of particular factor levels. As such they lack the flexibility of the *approximate* designs, described in the next section, which can be developed from the theory of Jack Kiefer. One example of the comparison of the designs resulting from the two theories arises in blocking response surface designs. Although blocking is usually less important in industrial experiments than in agriculture, batches of raw material, shifts of operators, and days of operation are often sources of heterogeneity that should be guarded against by blocking. In such designs, the sizes of the blocks are typically constrained by the number of units available within each block. The *approximate* theory can provide a design respecting these constraints which is also efficient for estimation of the response surface. However, the division of the set of experimental conditions for a rotatable design between blocks, with the requirement of orthogonality between blocks, can lead to designs which may not respect the number of units available for each block. The required design structure is then determining the scale and nature of experimentation, which should instead reflect economic and scientific goals.

A second contribution of Box to the theory of experimental design was the introduction of evolutionary operation (EVOP) in which industrial plants or processes are run not only to produce product but also to produce information. The basic insight was an analogy with the evolution of species in which small changes are continually occurring; only those changes that are beneficial are retained. The transfer to experiments is to operate at a series of conditions that are small variations on what are believed to be the best operating conditions. If these change slightly, the series of EVOP experiments will indicate the change to the new conditions of best operation. The variations in operating conditions need to be sufficiently slight that quality of product is maintained. However, as in natural evolution, the number of experiments is large so that even small effects will eventually be detected.

Jack Kiefer and Optimum Experimental Design

At much the same time as Box's work in the chemical industry, Jack Kiefer at Cornell University

approached experimental design from a more abstract point of view, which led to the powerful general theory of optimum experimental design. Instead of focusing on just one property of a design, Kiefer considered functions of the information matrix. The inverse of this matrix provides the variances and covariances of the parameter estimates; an experimental design maximizing the determinant of the information matrix minimizes the volume of the normal theory confidence region for the parameter estimates. Other functions of the information matrix lead to designs minimizing the maximum or average variance of prediction over a specified region, to designs focusing on good estimation of a few parameters, or to designs for choosing between models.

A major step forward in the theory was the use of *approximate* or *continuous* designs in which experimental effort was represented as a probability distribution over the points of the design. Combined with the convex nature of the design criteria, these continuous designs satisfy a *General Equivalence Theorem*. This provides easily verified conditions for the optimality of proposed designs and to efficient algorithms for the computation of many kinds of optimum design. The discrete designs needed for applications are found by integer approximation to the continuous design. The efficiency of these approximations is calculated relative to the optimum continuous designs and the most efficient approximation chosen.

This theoretical framework has proved extremely powerful in the construction of efficient designs in a wide variety of contexts. Blocking, mentioned earlier as being problematic for rotatable designs, is achieved through addition of extra parameters to the model describing the data. Numerical algorithms can be used to divide the trials between the blocks in the most efficient way, taking account of any constraints on the maximum size of the individual blocks due to the availability of material. In this way, the design is determined by the available resources rather than the design determining the resources that are required.

Many of the standard designs, such as two-level factorials, are optimum, often according to more than one criterion. These designs require numbers of trials that are powers of two. However, designs for two-level factors may be required

for other total numbers of trials. These can be found numerically; despite a slight loss in orthogonality, these designs are often of surprisingly high efficiency. Likewise, optimum designs can be found for irregular design regions and for nonstandard regression models, such as those in which the values of the factors are constrained by being the components of a mixture. The most appropriate numerical algorithm will depend on the particular problem. Numerical optimization methods for continuous functions are often most appropriate for response surface designs, whereas combinatorial methods are effective for the blocked treatment designs encountered in agriculture.

In linear regression models, such as those used in response surface studies, the parameters enter linearly. The theory can also be extended to finding optimum designs for more complicated models, including the models with nonlinear parameterization that result from chemical kinetics or from some dynamical systems. Further extensions include designs for generalized linear models, in which the response is not normally distributed; binomial and Poisson responses are of particular importance.

An interesting theoretical aspect is that optimum designs for nonlinear models depend upon the values of the parameters the experiment is intended to estimate. This must come from some form of prior information. Sequential experiments, in which the experiment is guided by the information accruing about the true value of the parameters, provide an objective source of prior information. Subjective prior information can come from the collective experience of scientists. In either case, the information can be used in one of two ways. In truly Bayesian designs, the maximization of the design criterion allows for a Bayesian analysis of the experimental results. In the more often used *pseudo-Bayesian* approach, the design criterion is simply maximized over the prior distribution of the parameters, ignoring the knowledge about the distribution of the responses given by the prior distribution. Much current work on experimental designs in medicine, genomics, and engineering is for nonlinear models. The elicitation and methods of incorporation of prior information are an important aspect of the design of efficient experiments in these fields.

Robust Designs, Computer Experiments

The theory outlined in the preceding section is for experiments that lead to understanding the effect of treatments or to modeling physical phenomena. In this context, a robust experiment is one that yields informative answers even if the physical situation is not quite what was expected. An example is the pseudo-Bayesian design of an experiment to estimate the parameters in a nonlinear model. The design is intended to have reasonable efficiency over a range of values of the parameters.

A second use of the term *robust design* is associated with the work of the Japanese engineer Genichi Taguchi, whose experiments aim at determining the robustness of products and processes to random variation through the inclusion of *noise factors* in experiments. One set of such investigations involves conditions of use: A car engine needs to work well not only in the carefully controlled laboratory conditions under which it is developed but also in a variety of weather conditions from very cold to very hot, from dry to humid, and from sea level up to heights at which oxygen levels are reduced. Such factors should be included in the experimental investigation of the properties of the engine. Similarly, machines may not be properly maintained and need to be insensitive to imprecise adjustments.

An extension of these ideas is to the manufacturing process itself. Here the idea, sometimes called *robust engineering design*, is to design the product so that its performance is insensitive to slight variations in the manufacturing conditions, such as might arise from batches of raw material, or production in different plants. In the analysis of possible designs, there are typically a large number of factors which may interact; the theory of multifactor experiments is crucial to finding a path to the product with greatest engineering robustness. The response to these experiments is typically the proportion of products that do not perform within specification. The analysis, and so the design, therefore involves generalized linear models rather than the normal theory models underlying Taguchi's statistical recommendations.

In robust design for products, rather than in the manufacturing process, the basic statistical

ideas of design are the same as those already described here. Improvements can be made in many of the original proposals of Taguchi by using more recent developments in experimental design, such as those associated with the methods of optimum design. This is in contrast with computer experiments which are methods for exploring the output of a deterministic system and so require a different theory from which to develop informative experiments. Many deterministic computer models, used for example in engineering design, involve large sets of differential equations with complicated boundary conditions. Almost invariably there are many inputs. There may also be many outputs, but this is less critical for the design of efficient experiments. A single run of the simulation model under one set of inputs can often take several hours. Because the model is deterministic, replicate experiments at the same combination of factors yield the same response. However, the outputs usually vary in a smooth way with the inputs, with adjacent inputs having similar output values. It is thus possible to build a simple model, an emulator using a derived response surface, from which the outputs can be determined for any specified set of inputs. Because there is no error of observation, the standard methods of optimum design, such as D-optimality, with their resultant emphasis on replication, are not applicable. One approach to experimental design in these conditions is to use designs that fill the space of the factors as precisely as possible. The theory underlying the designs is close to that used in determining good sequences of pseudo-random numbers that are, in fact, often required in stochastic simulations. A second approach is to assume that the responses form a Gaussian random field. Prior specification of the parameters of the field is required. A Bayesian design is then found which provides best average prediction over the region of interest.

This theory is for simulations without any stochastic component. Simulations with a stochastic component form a large part of statistical work. Examples include the investigation of the small-sample properties of statistical procedures for which asymptotic theory provides only large sample results and the investigation of complex systems such as those arising in weather modeling. The principles of experimental design described

in the earlier sections of this entry apply to the design of such stochastic simulations.

EXPLANATION

The nature of explanation is one of the most enduring problems of philosophy. Explanation has generally been associated with causation, in that when we are explaining an event or phenomenon we are identifying its cause. The ancient Greek philosopher Aristotle's theory of causation can be regarded as an early theory of explanation. At the beginning of the 20th century, the view that was dominantly held was that science cannot provide explanations of natural phenomena.

As the 20th century progressed, however, advances in the philosophy of science meant that a more rigorous independent analysis of the

concept of explanation became necessary. Explanation began to be seen as a primary goal of science. For the first time, new scientific theories about the existence of unobservable entities and processes—for example, atoms, genes, and fields—began to emerge. Traditional empiricists, however, had to resist treating these theories as *true*, because according to their view unobservables were merely posits, and claims about them could not be evaluated as true or false.

In order to resolve this dilemma it became crucial to find a way of characterizing these theories' obvious value while retaining the fundamental principles of rationality deemed central to science. There needed to be a distinction between *truth* and *explanation*.

Truth and Explanation

Theories of explanation can be either realist or epistemic (anti-realist). A *realist* understanding of explanation puts forth the idea that entities or processes posited by an explanation truly exist—and that the explanation is a literal description of an external reality. Realist interpretations hold that *truth* and the explanatory power of a theory involve matters of language which correspond to an actual external reality. This theory of explanation gives us *real* insight into the causal structure of the world.

An *epistemic* interpretation of explanation, in contrast, posits that unobservable entities or processes do not necessarily exist in a literal sense but can provide a useful means of organizing human experience. What we discover during a scientific experiment gives us the means to construct an empirical model—as opposed to furnishing a literal description of reality.

Someone who denies that scientific theories are explanatory in a realist sense does not necessarily deny that they are explanatory in an epistemic sense. And the same is true the other way around, namely, that someone who asserts that scientific theories are explanatory in an epistemic sense may (or may not) claim that they are explanatory in a realist sense. One way of looking at the distinction between truth and explanation is to say that theories that refer to unobservable entities may *explain* the phenomena, but they are not true in a *literal* sense. Put another way, we can say that these theories are true, but they do not in fact *explain* the phenomena.

In these two situations, we can see that the terms *truth* and *explanation* are being used differently in the two statements. In the former, the term *explanation* is being used epistemically and *truth* realistically; in the latter, *explanation* is used realistically and *truth* epistemically. Early 20th-century philosopher and scientist Pierre Duhem (1861–1916) aligned himself with the second interpretation, believing that a physical theory is not an explanation but merely a system of mathematical propositions deduced from a small number of principles representing a set of experimental laws. For Duhem, the basis of explanation involved stripping the reality of the appearance to get to the underlying reality. For him, explanation was the task of metaphysics, not science, since science cannot comprehend reality but exists simply to give order to appearance.

The later rise of analytic philosophy, in particular that of logical positivism, rendered Duhem's classic metaphysical stance unpopular. Logical positivism sought to legitimize philosophical discourse on a similar basis to that employed by the best claims of empirical science. An anti-realist movement—famed for seeking to purge scientific thought of any talk about nature's unobservable aspects, including mechanism, causality, and principles—logical positivism posed science as explanation.

Carl Hempel's Theory of Explanation

Carl Hempel (1905–1997) was a logical positivist, to whom many attribute the first robust theory of scientific explanation for contemporary science. Hempel was concerned solely with logical form and argument—without reference to any actual physical connections between phenomena. *Laws* play a key role in Hempel's concepts of explanation. Hempel's theory used the assumption that laws are *regularities* that meet conditions that are acceptable to empiricists.

In his view, to explain the phenomena in the world of experience was to answer the question “Why?” rather than “What?” This is one of the main objectives of rational inquiry—to go beyond mere descriptions of subject matter by providing an explanation of the phenomenon itself.

For Hempel, answering the question “Why?” did not (as it did for Duhem) involve appealing to a reality beyond experience. His “Why?” expressed

a desire to make predictions about future experiences, and for him the value of a scientific theory rested on its ability to do this.

Hempel proposed two models of explanation: The *deductive-nomological* (DN) model and the *inductive-statistical* (IS) model. Both have the same structure, with premises containing statements of two types: initial conditions C and lawlike generalizations L. The only difference between the two laws is that the laws in a DN explanation are universal generalizations, whereas the laws in IS explanations are statistical generalizations.

An example of a DN explanation containing one initial condition and one lawlike explanation follows:

C: The baby's cells have three copies of chromosome 21.

L: All babies with cells that feature three copies of chromosome 21 will suffer from Down syndrome.

E: The baby has Down syndrome.

An example of an IS explanation:

C: The man's brain was deprived of oxygen for 5 minutes continuously.

L: It is almost always the case that people whose brains are deprived of oxygen for 5 minutes will suffer brain damage.

E: The man has brain damage.

Hempel preferred DN explanations to IS explanations, because the deductive relationship between the premises and conclusion maximized the predictive value of the explanation. For him, IS arguments were explanatory only insofar as they approximated DN explanations by giving them a high degree of probability of explaining an event.

Hempel saw explanation as a concept that should be understood in terms of logic. A good DN explanation relies on there being true premises. But in order to qualify as a DN explanation, an argument needs simply to exhibit the DN structure. This illustrated Hempel's logical positivist position, which required that all epistemically significant scientific concepts should be analyzed in scientific terms.

When it comes to IS (based on statistics) explanations, however, their inductive character can always be undermined by the addition of new information. For example, in the earlier IS explanation, the case of

the probability of a man suffering brain damage may be reduced by the fact that he was submerged in a cold body of water. A proposed IS explanation, then, even if the premises are true, would fail to predict the fact and would have no explanatory significance.

Criticisms of Hempel's Theory

Hempel's lack of enthusiasm for statistical explanation was criticized by many modern scientists who saw its use for explanation as indispensable. This was because of the counterintuitive implication that for inherently low probabilities of events, no explanations are possible.

For example, it may not hold statistically that smoking three packs of cigarettes a day for 30 years will lead to a person's contracting lung cancer. If we follow Hempel's theory, it follows that a statistical law about smoking cannot be used to explain the occurrence of lung cancer, a position which is at odds with what we know about smoking and lung cancer.

Hempel might counter this by stating that when our theories do not allow us to predict a phenomenon with a high degree of accuracy, it is due to our incomplete knowledge of the conditions. However, this still puts us in the uncomfortable position of having to base a theory of explanation on the dubious metaphysical position that all events must have determinate causes.

Hempel's view was also criticized because DN arguments that have true premises may be unexplanatory. According to Wesley Salmon, the relevance of this problem is as follows:

Ci: Adam takes birth control pills.

Cii: Adam is a man.

L: Men who take birth control pills do not become pregnant.

E: Adam does not become pregnant.

While this qualifies as explanatory according to Hempel's theory, the premises are obviously explanatorily irrelevant to the conclusion.

Sylvain Bromberger (1924–2018) took Hempel to task on the question of asymmetry: On the one hand, Hempel's model can explain the period of a pendulum in terms of the length of the pendulum together with the law of simple periodic motion; simultaneously we can explain the length of the

pendulum in terms of its period in accord with the same law of motion. Intuitively, we may feel that the first is the proper explanation, while the second is not. We can make the same point in the following way:

C: The barometer is falling rapidly

L: Whenever the barometer falls rapidly, a storm ensues

E: A storm is imminent

Despite the fact that the falling barometer indicates the storm's approach, it is counterintuitive to state that the barometer *explains* the approach of a storm. It is instead the approaching storm that *explains* the falling barometer.

These problems of relevance and symmetry reveal how difficult it is to present a theory of explanation that has no relation to causality. Hempel cannot have causal relations as an option, since causation is at the top of the list for the anti-realist's view of metaphysically suspect concepts. Involving causality would also undermine the view that explanation can be understood in terms of an epistemic, rather than a metaphysical, relationship. Hempel responded by stating that whether explanation has a practical value is not something that can be determined via philosophical analysis. This reply, although adequate, did not satisfy his critics.

Lawlike and Accidental Generalizations

Hempel's model of explanation requires there to be at least one lawlike generalization. This also presents a problem for the DN model. Hempel distinguished between lawlike generalizations and accidental generalizations, the latter being those that might be true but not as a result of a law of nature. For example, when saying "All my shirts need ironing," we are stating an accidental fact rather than an event that is subsumed under the laws of nature.

This makes it doubtful whether Hempel's epistemic view of explanation can be considered consistent, since there is no epistemically sound way of distinguishing between lawlike generalizations and accidental generalizations. No finite number of observations can back up the claim that a natural regularity is due to a natural necessity. In the

absence of such a criterion, Hempel's model does not appear to fit with an epistemic view of explanation, and that explanation can be understood in purely logical terms.

Contemporary Explanation Theory

With the decline of logical positivism and the increasing success of modern theoretical science, arguments about whether unobservable entities existed became redundant. Explanation as attributable to a cause came back into fashion.

Wesley Salmon's (1925–2001) influential realist causal account of explanation takes the view that real processes and entities are conceptually necessary in order to understand why explanations work. He rejected all epistemic theories of explanation as incapable of being able to bring about adequate scientific understanding.

For Salmon, scientific understanding is not just concerned with being able to hold justified beliefs about the future. He argued that even someone with a near-perfect knowledge of all natural laws and universal conditions and in possession of perfect predictive knowledge would potentially still lack scientific understanding. Having predictive knowledge does not entail having awareness of concepts such as causal relevance that are essential to allow insights into true causal processes and pseudo-processes.

Salmon's causal realism rejects Hume's influential concept of causation which imagines a series of linked chains of events. Instead he sees causation as a continuous series of causal processes and interactions or set of instructions for producing an explanation of a particular event or phenomenon. By starting with a list of statistically relevant factors, then analyzing these factors we end up with a causal model of statistical relationships, which can be empirically tested in order to select those which best support the evidence. This is a *reductionist theory* which rests on finding the causal mechanisms of a phenomenon. Salmon's theory does not lend itself easily to explanations of mental events however which do not appear to be easily reducible to a set of causal relationships.

Like Hempel, Salmon's theory was an ideal or higher form of explanation theory, and these kinds of theories of explanation began to be criticized for failing to resonate with scientists or ordinary

people in their everyday lives. Another approach to explanation involved the relationship, beliefs, and intentions used by people on a day-to-day basis.

Explanation as a Form of Communication

As well as these theoretical and essentially scientific approaches to explanation theory, certain philosophers have grounded their understanding of explanation in the way in which people perform the act of explanation. This so-called *ordinary language philosophy* focuses on the linguistic and communicative aspects of explanation. This involves answering questions with the aim of furthering the understanding between individuals.

Peter Achinstein developed an *illocutionary* theory of explanation, which defined the act of explanation as the attempt by one individual to produce understanding in another by answering certain kind of questions in certain ways. He rejected Salmon's narrow interpretation of explanation and its association with causation. According to Achinstein, we attempt to gain understanding by asking different questions such as "Who?" "What?" "When?" and "Where?" in order to find explanations.

Whereas traditional theories of explanation attempted to understand the *logic* of explanation, Achinstein tried to describe the *process of explanations*. For example, when a person asks for an explanation of "why the lights in the house have gone out," they implicitly formulize their question in such a way so that they will receive a reply that will enable them to turn them back on again. The explanation they require must practically help them put the lights back on. Receiving an answer in terms of, say, mathematical equations would be of no help to them—but must be provided in a practical understandable manner.

Achinstein ruled out tautological answers as explanations too, for example, "Mr. Smith died because he ceased to live" as being of no explanatory use. He also counted as nonexplanatory, non-relevant, and noncontextual answers to scientific questions. For example, if we ask, "What is the speed of light in a vacuum?" and receive the answer "186,000 miles per second" we have not been given a satisfactory explanatory answer but simply a large number with no comparative reference to velocities that mean anything to us.

Naturally this does not mean that the speed of light cannot be explained—it's just that the answer needs to be framed in terms that we can relate to, for example, "light can travel around the earth eight times a second."

Achinstein has been criticized for being somewhat vague when it comes to exactly what are *content-giving* propositions. He failed to narrow down a list of questions which would qualify as requests for explanations, making it difficult to identify what it is specifically about any act of explanation that enables it to produce understanding. It's also difficult to infer that simply asking for a certain kind of knowledge will actually lead to achieving the desired knowledge.

Cognitive Science and Explanation

Another departure from standard relational analysis of explanation can be found in cognitive science. A cognitive approach to explanation maintains that an explanation is a kind of mental representation that results from or aids this understanding. There are divisions in the field of cognitive science as to whether explanation is conceived as the process and result of belief revision—or whether it is the activation of patterns in a neural network that provides the basis of explanation.

The latter perceives the act of explanation as a purely cognitive activity and explanation as a mental representation resulting from or aiding this activity. Explanation is thereby considered a universal phenomenon which can be conscious and deliberate or unconscious and instinctive, requiring no explicit propositional knowledge.

For example, a mother hearing a high-pitched cry coming from her child's room will immediately rush to that room to come to their aid. This act could be described as instinctive or based on inference, but whatever the reason we can say it was as a result of the mother having *explained* to herself the crying noise as that of the crying of their child. This gives explanation a theoretical rather than a logical or metaphysical status.

Mental Models

One approach used by cognitive scientists incorporates both traditional belief-desire aspects and neuroscience resulting in the idea of a mental

model. The term was first put forward in 1943 by Kenneth Craik in his book *The Nature of Explanation*. In his book, Craik suggested that the mind constructs *small-scale* models of reality that it uses to anticipate events. Mental models arise from mental representations that result from the activation of an aspect of a network of condition-action (if-then)-type rules.

When clustered together, these conditions (rules) apply to get action results. They rest on the assumption that reasoning depends not on logical form as used in formal rule theories but on models constructed from perception and imagination, somewhat akin to a physicist's diagram in that the structure is analogous to the structure of the situation that it represents.

Based on a small set of fundamental axioms or assumptions, each mental model represents a possibility, capturing what is common to all the various ways in which the possibility may occur. Mental models are based on a principle of truth, since all the possibilities represent what is true according to a proposition. Individuals infer that a conclusion is valid if it holds in all the possibilities, and counterexamples act to refute valid inferences. Critics of mental model theory include those who cite deduction-based theories based on inference rules rather than relying on models.

Naturalism and Explanation

Naturalism is associated with the rejection of any kind of explanation of natural phenomena that refers to unnatural phenomena. Many naturalists embrace the idea of inference as the best form of explanation, as a fundamental principle of scientific reasoning. They hold that if we treat the existence of unobservable entities as a scientific hypothesis, then this can provide an explanation of the success of the theories that employ them. In contrast anti-realism cannot provide such an explanation since they view theories that refer to unobservable entities as literally untrue and the success of scientific theories unknowable. As mentioned at the start, traditional realists, unlike scientific realists, do not think of realism as a scientific hypothesis but as an independent metaphysical thesis.

The State of Explanation Theory Today

Our knowledge of the nature of explanation has improved since its beginnings, with each new model giving us pause for thought. Whether it is possible to construct a single model of explanation to fit all areas is a moot subject, since the types of explanatory goals—the sorts of explanatory information sought and what is thought to be achievable, testable, or discoverable—vary so widely across disciplines. In future, it is predicted that models of explanation will be developed that are sensitive to disciplinary differences.

Ideally, these models should also reveal commonalities across disciplines as well as allow us to see why explanatory practice varies along with its significance. For example, biologists often describe their explanatory goals as the discovery of mechanisms, while physicists talk about explanatory goals in terms of laws. While this may just be a purely terminological difference, it may also be the case that we need to uncover the background to what a mechanism is, as understood by a biologist, and how this can impact on a theory of explanation.

F

FACT VERSUS THEORY

The relationship between *fact* and *theory* is a matter of controversy in science and in the philosophy of science. Such controversies stem from the debate between different varieties of realism/scientism and antirealism/antiscientism and their different ontological and epistemological assumptions. A first controversy arises as to whether the use of facts as conditions, criteria, and rules for establishing justified true belief (i.e., a belief's epistemic value) is or is not a distinctive aspect of scientific theories regarding other kinds of theorizing (e.g., common knowledge, history, journalism).

In this vein, antiscientism (e.g., Paul Feyerabend) asserts that appeals to facts—a distinctive feature of scientific theories—are no more than *rhetorical bullying* (i.e., *nominal identity* between scientific theories and other kinds of theorizing). Susan Haack's *critical commonsensism* supports the thesis that science is not radically different from other kinds of inquiry in the use of evidence: Epistemic values, chief among them respect for facts, are also relevant to other forms of theorizing (i.e., *difference of degree* between scientific theories and other forms of theorizing). Finally, scientism (e.g., Alexander Rosenberg) postulates that the very meaning of scientific inquiry is to build and control theories on factual entities inaccessible to common knowledge and other forms of theorizing (i.e., *nominal difference* between scientific theories and other forms of theorizing).

A second controversy on the relationship between fact and theory arises from the very definition of fact—particularly whether a fact is considered equivalent to a *phenomenon*. The different answers to this question can be synthesized in the debate between phenomenalism (as a variety of antirealism) and scientific realism (as a variety of realism). Phenomenists have defined facts as the collection of those entities that are the object of experience, that is, *phenomena*. In a different manner, scientific realists look for facts behind phenomena (or appearances), which they postulate are accessed through reason. For scientific realism, a phenomenon is the class of *observable* facts that is characterized by being an event accessed through the senses, which, together with the class of *unobservable* facts accessed through reason or nonsensory intuition, constitute reality. In short, for scientific realism, *phenomenon* and *fact* are not synonymous; a phenomenon is only a class of fact. For phenomenalism, fact and phenomenon are equivalent; facts consist of phenomena.

A third controversy on the relationship between fact and theory results from the definition of theory, specifically of scientific theories. For scientific realism, given its ontological assumptions, any project of scientific theory that is not trivial must have the objective of discovering what lies beneath what is observable. Observable facts are real but only superficial. Because they are superficial, they must be explained in terms of unobservable facts that are capable of being scrutinized, and they

must be scrutinized via scientific theories. For phenomenalism, given that reality is accessed inevitably through the intersection between subject and object, the world is dependent on the subject; the scope of scientific theories is circumscribed inherently to those facts to which we have access through experience. Thus, scientific theories are conceived as giving descriptions of observable entities in a subject-dependent world.

A fourth controversy emerges on the intertwining of theory and fact in the production of useful scientific results. Two questions stem from this debate. First, to what extent do scientific theories represent and explain facts? Second, what place do facts have in testing scientific theories?

Regarding the first question, scientific realism has affirmed that scientific theories can produce (fallible) objective truths about at least some facts (epistemological realism). Antirealist traditions, with some variations among their theses, deny the possibility of objective truth (epistemological skepticism). Hence, one variety of antirealism, postmodernism (e.g., Jean-François Lyotard), proposes that scientific theories are *metaphors* rather than representations of facts. Another variety of antirealism, constructivist relativism (e.g., Bruno Latour and Stephen Woolgar), posits that science is a form of fiction or discourse equivalent to any other, such as a literary text. Other alternative to scientific realism is constructive empiricism (e.g., Bas van Fraassen). Constructive empiricism is a contemporary—and influential—variety of phenomenalism, which postulates that science aims to produce theories that are *empirically adequate* rather than true, where a theory is empirically adequate if what this theory affirms regarding observable phenomena (i.e., those entities that can be directly observed by the human eye) is true.

Regarding the second question, a variety of realism, naive realism, postulates that the truth values of scientific theories derive from their testing with facts. By contrast, other philosophers—such as Norwood Russell Hanson, Thomas Kuhn, and Stephen Toulmin—have argued that because theory is a tribunal of what is considered fact, facts cannot be used to test a theory without committing to that very theory (the *problem of circularity*).

Ontological Status of Fact and Epistemological Status of Theory

The epistemological status that we assign to scientific theories depends on how we conceive of facts' ontological status. As Mario Bunge maintained, epistemology is the result of ontology: depending on what is believed to be in the world, what is believed about what it is possible to know and how to know it are derived.

Regarding the notion of fact, a fundamental difference emerges between realism and antirealism on how *properties* of facts are conceived ontologically. Following the Kantian distinction between *noumena* (or things-in-themselves) and *phenomena* (or things-for-us or things as perceived), scientific realism holds that facts have two types of properties: primary and secondary. Primary properties are objective or subject-independent, and secondary properties are subjective or subject-dependent. For example, the wave frequency of sound is a primary property because it is found in the world (i.e., it is subject-independent), whereas the tone is a secondary property because it emerges in the ear–brain system (i.e., it is subject-dependent).

By contrast, according to varieties of antirealism, primary or objective properties would be derived, imaginary, or (in the best of cases) inaccessible to knowledge. Thus, classical varieties of antirealism either deny the independent existence of the physical world and affirm that only the mind and its ideas exist (George Berkeley's subjective idealism) or do not admit more reality than that of experience, understanding by such the set of subjective perceptions (Edmund Husserl's ontological phenomenalism).

In particular, phenomenalism casts doubt on whether we can access something unobservable. Phenomenalists reduce the world to what Ernst Mach called *a complex of sensations* and claim scientific theories describe only observable facts. To a large extent, Rudolf Carnap's unsuccessful attempt to eliminate theoretical terms and leave only observational terms derived from the phenomenalist ontology—and from the antimetaphysical program—that characterized logical empiricism (or logical positivism or neopositivism: these labels are used interchangeably here). In short, and according to phenomenalists, the world

would be reduced to secondary properties (ontological phenomenalism), and sensible human beings would get to know the world through common experience (epistemological phenomenalism). Denying the existence or accessibility of the primary or objective properties, scientific theories must be directed to the study of the secondary properties or phenomena.

In other words, scientific realists recognize the ontological and epistemological statuses of primary properties and secondary properties, whereas phenomenalists recognize only the ontological and epistemological statuses of secondary properties (which the latter call *experience* or *appearances*). In this way, phenomenalism maintains the following: (a) The properties of facts are circumscribed to those of sensible experience (i.e., secondary properties for scientific realism) and (b) if there were primary properties, then we could not access them because inherently we know the world through the subject–object interface. By contrast, scientific realism states the following: (a) Facts have both primary and secondary properties (the former are found in the world, and the latter are found in the brain), and (b) we can access the primary properties through reason, nonsensory intuition, and especially scientific theories.

Nevertheless, for scientific realists, the ontological and epistemological statuses of facts' primary and secondary properties are more complex. In ontological terms, scientific realism claims there are no secondary properties in the physical world. There are no colors, smells, or tastes in the external world, because they are located in the subject–object interface. Thus, all secondary properties require two sources: the brain and something else in the world. Hence, although some primary properties (e.g., chemical composition) are intrinsic, all secondary properties (e.g., taste or smell) are relational; they are all only for us, and none exists in itself. Consequently, the ontology of most secondary properties of facts requires the inclusion of the brain. Without brains, most secondary properties would have no existence as such.

In epistemological terms, scientific realism asserts that scientific theories do not contain concepts denoting secondary properties—unless secondary properties are their object of study, as is the case with psychology. Scientific theories (e.g., of physics, chemistry, biology) describe noumena

(i.e., physical things), not phenomena (i.e., mental processes)—unless mental processes are their object of study, as is the case with neuroscience. There is no trace of phenomena (appearances to a sensitive being) or secondary properties in the formulas of physical theory. No scientific theory contains variables denoting secondary properties (colors, for instance).

In addition, scientific realists have proposed that scientific theories cannot explain secondary properties (e.g., the taste of food) without primary properties (e.g., the chemical composition of food). For example, it is impossible to explain a secondary property of lemons, such as their acid taste—which our taste buds recognize—without taking into account a primary property of lemons—that is, that they contain hydrogen ions.

Fact, Theory, and Epistemic Justification

A fundamental nexus between fact and theory is related to the problem of the epistemic value of theory. The epistemic value of a theory involves the central problem of when and how we are justified in holding that theory to be true. Regarding fact, a question that emerges about the epistemic value of a theory is whether, how, and to what extent facts justify its truth. This question is considered particularly meaningful in assessing the epistemic value of scientific theories.

Although the postulated epistemic relationship between scientific theory and fact varies according to different philosophies of science, a long tradition has maintained that a theory is considered scientific when it proposes a certain set of refutable hypotheses—that is, when a theory seeks to confirm or disconfirm its adequacy to the facts. The correspondence between fact and theory has been considered by both verificationism (i.e., a given theory is scientific if it entails verifiable observable consequences) and falsificationism (i.e., a given theory is scientific if it has falsifiable observable consequences) as a meaningful criterion for the epistemic justification of scientific theories and as a demarcation criterion between the scientific and the unscientific. Science systematically seeks to determine whether facts confirm or falsify theories. Thus, the use of empirical evidence (i.e., facts) distinguishes science from other, nonscientific, cognitive endeavors.

However, more contemporary philosophers of science have emphasized that the links between fact or the factual state of affairs (i.e., nonconceptual entities) and theory (i.e., a conceptual entity) are more complex. First, sentences, not facts, confirm or disconfirm theories. One important consequence of the *linguistic turn* in philosophy—frequently associated with analytic philosophy—has been to concentrate a theory's epistemic value on the logic of observation rather than on objects or facts. Hence, a scientific theory is conceived as a system of sentences or sentence-like structures (e.g., propositions, statements, claims) to be tested by comparison with observational evidence. Consequently, it follows that theories are tested not against facts but against sentences or propositions on observed things.

Second, the problem of the relationship between fact and theory makes sense in the factual sciences, not in the formal sciences. In this vein, some approaches fail to distinguish between two different sorts of truth, that is, formal truth (proper to the formal sciences) and factual truth (typical of the factual sciences). On the one hand, a formal science is by definition a discipline that contains only formal propositions (e.g., mathematics, logic). On the other hand, a factual science is by definition a discipline that contains at least some factual propositions; they are the sciences that describe, explain, or predict things or events that belong to the real world, natural or social (e.g., natural sciences, social sciences).

Therefore, in the formal sciences, (a) objects (e.g., mathematical and logical entities) are defined in a purely conceptual way without resorting to any factual or empirical means, and (b) formal proofs and refutations (e.g., logical and mathematical theorems) are strictly conceptual processes that do not make any reference to empirical entities or facts. Consequently, in the formal sciences, theory is epistemically independent of fact because formal truth depends only on logical rules of inference. Thus, an epistemic relationship between fact and theory makes sense only in the factual sciences.

Third, confirmation theory—simply defined as the study of the logic by which scientific theories may be confirmed or disconfirmed by evidence or facts—has proven a rather difficult endeavor. The ideas of many philosophers of science, such as

Pierre Duhem and Willard Van Orman Quine (and, more recently, for the Bayesian confirmation theories), have challenged the venerated confirmation theory of Carl Gustav Hempel. In particular, the governing idea in traditional confirmation theory, according to which each statement taken in isolation can admit confirmation or disconfirmation, is questioned as a form of reductionism. This idea has been criticized on two main grounds. First, because empirical statements are interconnected, they cannot be disconfirmed singly (the Duhem–Quine nonseparability thesis). Second, and as a corollary, empirical evidence tests a theory as a *corporate body*. As a consequence, if a theory is falsified, then it is impossible—at least in some sciences—to investigate where the error lies (the Duhem–Quine nonfalsifiability thesis).

Fourth, an additional difficulty for the epistemic value of fact versus theory emerges from the idea that observation is permeated inherently with theory, which thus has weakened the fundamental distinction between theoretical terms and observational terms. Observational terms garnered special epistemic status because they seemed more direct and therefore less distorted than theoretical terms. In physics, the conception according to which experiments show observation to be completely permeated by theoretical terms has gained acceptance: Observation is theory-laden to the point where, as Pierre Duhem observed, it becomes impossible to express fact in isolation from theory. In neuroscience, it has been increasingly difficult (if not impossible) to reconcile the idea of highly processed data such as functional magnetic resonance imaging pictures with the search for a pure observational language. The consequence of those developments in the factual sciences is an increased blurring of the distinction between theoretical terms and observational terms, which makes it difficult to accept both that a theory can be tested with observational data and that it can be asserted that Theory A accounts for the facts better than does Theory B.

Fifth, other philosophers of science—such as Thomas Kuhn—have argued that the meanings of terms are determined by a certain theory or a *paradigm* to the point where even the same terms cannot be compared in various theoretical contexts because their meanings depend intimately on, and vary with, each theoretical context. For

example, because Newton's theory is based on a paradigm different from that of Einstein's theory (according to Kuhn), terms such as *mass*, *space*, and *time* have different meanings per each theory. An epistemic consequence of the Kuhnian approach is that it calls into question the idea that it is possible to judge each theory against the other in light of observed facts.

Finally, some philosophers, such as Stephen Toulmin, have raised the problem that facts (i.e., their observation) are not accessed directly but through *ideals* or *ideals of natural order*, that is, through theories that establish what are considered *facts*. Consequently, the theories themselves establish the facts against which the theories are subsequently tested. In the factual sciences, the theory is not related to the facts merely for their confirmation or disconfirmation; rather, the theory provides the framework for what are regarded as facts. In this sense, the claim is that none of the factual sciences apprehends its object as it is but as its own analytical operations modify that object. For this reason, the factual sciences are said to transcend facts—they discard some and produce new ones. Furthermore, in the factual sciences, theory is a tribunal of what is regarded as fact.

Accordingly, the relationship between theory and fact is twofold. On the one hand, the facts are used to confirm or disconfirm a theory; on the other hand, the theory establishes those parts of reality that are considered facts. Last, because of the paradoxical relationship between fact and theory, some philosophers of science—such as Karl R. Popper, Norwood Russell Hanson, and, more recently, Allan Franklin—have worried that drawing upon theoretical assumptions from the very theory to be appraised yields vicious circularity.

FALSIFIABILITY

Falsifiability focuses on theory disconfirmation using deduction, and application of this epistemology and method signifies a science, according to the tenets of critical rationalism, formulated by Karl Popper (1902–1994), a philosopher of science. Popper received much

acclaim during his lifetime, although many recently published philosophers have distanced themselves from his ideas. In contrast, most contemporary scientists and social scientists with a research focus are strongly influenced by his thoughts on scientific methods, including falsifiability. Before presenting the concept, some information about the philosopher is provided, since biographic factors played a role in Popper's theoretical formulations.

Karl Popper

The philosopher was born and educated in Vienna, Austria. In later recollections of these early years, Popper recalled Albert Einstein's (1879–1955) Vienna lecture of 1921, which he attended at the age of 19. Einstein's discussion of the theory of relativity resonated with Popper, especially since the British astronomer and physicist Arthur Eddington (1882–1944) had led an expedition to Principe, a West African island, to observe the 1919 solar eclipse, vindicating the theory, although the expedition also had potential to negate the theory. This final point was one of many stimulants suggesting to Popper that falsifiability rather than testability was the correct way to move scientific endeavors forward.

Other important links in Popper's philosophical path toward his later views of science were his early interactions with admirers of Alfred Adler (1870–1937) and Sigmund Freud (1856–1939), both medical doctors, active in Vienna, and founders of psychoanalysis. Popper had volunteered with disadvantaged children, and in the process, took a patient study to Adler, who managed to slot the case into his theory in a process that Popper later considered to be intellectually dishonest.

In contrast to his later reevaluation of the psychoanalysts, Popper maintained greater respect for a group of psychologists involved in the Würzburg school, based in Würzburg, Germany, specifically Oswald Külpe (1862–1915) and Otto Selz (1881–1943). Selz instructed Popper, who later incorporated his teacher's thesis that problem-solving is essential to processing ideas into his definition of science.

A fourth key event during Popper's youthful years was his involvement with Marxism, before Austrian government changes engendered his

realization of how political extremism curtailed freedom and destroyed lives. Popper's parents had converted to Protestantism from Judaism, and in the anti-Semitic climate of Austria, leading up to the Nazi takeover of Europe, and World War II, his family's Jewish background became significant. Indeed, the Nazis killed many of his relatives, although Popper managed to leave Austria and was spared.

Science

Popper's 1934 book *Logik der Forschung* remained inaccessible to English speakers until 1959, when *The Logic of Scientific Discovery* was released. The English version was an unamended translation of the earlier publication, with appendices and footnotes augmenting the original book. Popper favored a clear, succinct manner of writing, and for the most part, his work is accessible to scientists and social scientists, not just philosophers.

The Logic of Scientific Discovery focused on how science should move forward, both epistemologically and methodologically. According to this perspective, science is not static but constantly progressing as theories are falsified and alternatives proposed in their place. Popper was not presenting the history of scientific advances as a descriptive exercise but rather prescribing how science should proceed, with a strong empirical basis. He presented a problem-oriented science based on deductive reasoning.

In this book, Popper reviewed his earlier fascination with Marxism and psychoanalysis, critiquing their methods as unscientific. In contrast, he pointed to Albert Einstein's work on gravity, with its risks of falsification by the 1919 solar eclipse data.

Popper was interested in the context of justification, specifically how theories are explained and then examined through comparisons with the real world. He did not deal with the context of discovery, which covers how theories are created, and what inspiration or thinking process underlies their formulation.

He demarcated a clear boundary between scientific and nonscientific theories and claimed that the limits of science were determined by the use of falsification. This means that scientists must

consider how to disprove their theories and attempt to the best of their abilities to apply empirical evidence to this end. Popper used the analogy of a net in his discussion of theory, with the throwing of the theoretical net into the world signifying the attempt to understand reality. As science advances, the net mesh size is gradually narrowed, meaning that the world is comprehended in greater detail, with continual skepticism as the procedure continues. However, there is never certainty to this process, since a theory is only accepted so long as it has not been disconfirmed, and there is always the potential of future disconfirmation.

In contrast, positivists, such as the members of the Vienna Circle encountered in Popper's youth, believed that the weight of accumulated positive tests of a theory provided greater justification for the theory being correct. Maintaining the image of the net, such an approach would thicken the net's mesh, rendering it ever more improbable that disconfirmation could ever occur, and supporting a more static scientific universe.

Popper's ideas about demarcating the boundary between science and nonscience were challenged by Imre Lakatos (1922–1974), a colleague at the London School of Economics. Their initially friendly relationship was marred when Lakatos published increasingly radical amendments of Popper's ideas. Lakatos felt that Popper's criterion of falsifiability as key for a science was too inflexible, and he suggested that various degree of falsification might occur in science, as practiced by actual scientists. He also suggested that there might be higher degrees of falsification during some time periods, with lesser gradations at others.

Using Popper's metaphor of the net of science, including the key element of falsification, it is apparent that according to his reasoning, psychoanalysis is not scientific because there is no evidence that can be presented to prove it incorrect. However, the discipline may be considered a pseudoscience, since with some modifications, such as the addition of falsification to examine it, there is potential for it to become scientific. In contrast, the cases of astrology, phrenology, and other forms of fortune telling are simply unscientific, since there is no way to create tests to disconfirm them. They depend on belief. In order to be a science, a field of

study must use a scientific method, incorporating falsification and deduction.

Popper's use of falsification as key to defining a science has received some pushback from academics and support by the courts. In 1981, Judge William Overton ruled in an Arkansas case that falsifiability, as understood by Popper, was one of the four key pillars to determining a science. This meant that creationism, the belief that the universe and life originated from supernatural acts of divine creation, as in the biblical account, did not have to be taught in schools' biology classes. Within 6 years, a Louisiana case was ruled similarly in the Supreme Court. Falsification also appeared in those court documents. Michael Ruse, a philosopher, wrote about both cases.

In an interesting twist outside the court, recent examinations of astrology by scientists have used falsification as a way to disprove its scientific validity. However, semantically, for Popper's definition of a pseudoscience, this very application of deduction moves astrology into the category of a science, as clearly presented by Hansson. This suggests that some reconsideration of Popper's definitions may be overdue, which moves the discussion into the next topic.

Scientific Method

As mentioned previously, Karl Popper presented his prescriptive scientific method in *The Logic of Scientific Discovery*. He focused on the investigative methods of research, rather than the theory formation portion of the exercise. While positivists encouraged scientists to confirm hypotheses and theories, Popper moved in the opposite direction, upholding the necessity of falsification for a true science and specifying the method to be used.

In his treatise on method, Popper cited the work of the astronomers Johannes Kepler (1571–1630) and Galileo Galilei (1564–1642). This was not an attempt to recount the history of science; instead, he was promoting the idea that his ideas about science, and its dependence on falsifiability, are demonstrated in the reasoning of Kepler and Galileo (using his first name by convention) when they disconfirmed the suggestion that the sun revolved around the earth, thus supporting a heliocentric theory of the

universe. Popper also revisited the writings of Xenophanes (ca. 540–478 B.C.E.), a Greek philosopher, and claimed some support from this work for his methods.

Only a few years later, in 1962, Thomas Kuhn (1922–1966) presented *The Structure of Scientific Revolutions*, which also covered the work of Kepler and Galileo, although with a different focus. Kuhn argued that scientific revolutions occur with paradigm changes involving the sociology of the field, rather than according to the scientific merits of theories.

Popper, however, was completely uninterested in sociological interpretations of theory development and focused instead on the type of language applicable to the presentation of hypotheses, terming these *universal statements*. In some of his examples, he also allowed the substitution of mathematical symbols for words, based on a similar formatting style. Universal statements were examined by deductive reasoning to create means for disconfirming hypotheses, rendering the method scientific.

Deduction is working from universal statements to suggest a prediction, which can be experimentally examined with real-world data, and will serve to disconfirm the hypothesis. In contrast, *induction* is working from observations to a logical statement of the observations, often considered to be the truth of an event when presented by an observer. For example, if someone watches waves breaking on the shore, then it would be possible to formulate a theory about the size of the waves and their speed to calculate the amount of shoreline deposition or erosion. A theory based on these data, however, is difficult to disconfirm using the same information.

Despite Popper's focus on deduction, it is clear that many scientists and social scientists use a combination of induction and deduction as they apply the scientific method to real-world problems. For example, an archaeologist might use ideas about how human settlements function, based on debris patterns in one part of the world to suggest testable hypotheses about ceramic deposition at a site in another region. These hypotheses would be examined with archaeological excavation and analysis, in a process using induction, deduction, and testable hypotheses, along with falsification attempts.

To encourage well-founded attempts at falsification, Popper encouraged the incorporation of

high empirical content in theories. Enhanced falsifiability options occurred with theories pertinent to more real-world scenarios, since this would provide more opportunities to examine them with data. In addition, greater exactitude in predictions also improved the falsification exercise.

Popper also wrote about the importance of intersubjective testability, namely that all observers of the phenomena should be able to record the same results. In order for a theory to be disconfirmed it needs to be replicably falsified. In theory, falsification can occur with one negative instance, but Popper suggested that falsification should be repeatable under experimental conditions. This allows for falsification errors based on equipment failures or experimenter inexperience.

In conclusion, given the specificity of Popper's ideas and his somewhat rigid methodological stance, it is perhaps not surprising that philosophers have challenged his theory, while scientific experimenters outside philosophy have been more accepting of the broad sweep of his ideas. More recently, Popper's demarcation between science and pseudoscience has played an influential role in the legal and academic battles to remove creationism from public school curricula and has moved his terminology into a new arena. Falsifiability is likely to remain an important concept in the coming years.

FORMAL SCIENCES

Formal sciences are disciplines based on formal systems. These include logic, mathematics, and the theoretical fields of information theory, statistics, and computer science. Also included in the formal sciences are such areas as game theory, decision theory, and some areas of linguistics. Formal sciences use *a priori*, as opposed to empirical, methodology. Major advances in formal science have often led to major advances in the empirical sciences. The formal sciences are essential in the formation of hypotheses, theories, and laws and help us discover how things work, how people think and act.

Formal sciences are often considered the third branch of science, alongside natural science and social science. They came into existence long before the formulation of scientific method, since we know of mathematical texts dating back to ancient times. These include texts relating to Babylonian mathematics from around 1800 B.C.E., from Egyptian mathematics dating from around 1600 B.C.E., and examples of Indian mathematics dating back to around 1000 B.C.E. Other cultures have added their input along the way, including the Greeks and Islamists, as well as the Chinese and Japanese, who worked independently from one another.

Hundreds of years later, a branch of formal science called *logic* came into being. Like mathematics, logic originated from multiple cultures and methods. The first record of logic arose in India in the 6th century B.C.E., followed by China in the 5th century B.C.E. Modern logic originated from Greece and then Islam. It was during the 17th century C.E. that mathematics reached its zenith, with the earliest

studies of probability theory. Formal science in the modern world is now used in engineering, computer science, and many other disciplines.

This entry describes how the formal sciences developed, starting with the backbone of all the formal sciences, mathematics, and its various branches. Then the foundations of logic as a formal science, and its development, are examined and discussed the ways in which formal sciences are helping to shape the modern world.

Why Formal Sciences Differ From Other Sciences

One reason that mathematics, in particular, enjoys a special distinction above other sciences is because its laws are absolutely certain and incontrovertible. Those of other sciences are open to debate, and their theories in danger of being overthrown in favor of newly discovered facts.

As opposed to empirical sciences—the natural and social sciences—formal sciences do not involve themselves in empirical procedures. They do not presuppose knowledge of contingent facts or describe the real world. In this way, formal sciences are logically and methodologically *a priori*, their content and validity wholly independent of empirical procedures. Although formal sciences are conceptual systems, this does not place them apart from the real world, and they certainly have a relationship with it.

Formal statements can have a place in all possible, conceivable worlds; for example, there are a wide variety of mathematical axioms that categorize different incompatible worlds. This is in contrast to empirical theories, for example, the theory of relativity or evolution. These theories do not hold in all possible worlds, and in fact may not even turn out to hold in this world. It is this universal property that makes the formal sciences applicable to all domains and useful to all empirical sciences.

Formal sciences, being nonempirical in nature, are structured in terms of sets of axioms and definitions from which other statements (theorems) can be deduced. Put another way, theories in formal sciences contain no *synthetic* statements (those based on our sensory data and experiences), simply *analytic* statements, which are true by definition and are self-explanatory.

Foundations of Modern-Day Mathematics

Mathematics as a formal science is the cornerstone of the other formal sciences—indeed, they could not exist until mathematics had developed into a relatively advanced form of study. From the very early history of mathematics, mathematicians believed that the physical world was constructed along mathematical lines. Pythagoras (c. 570–490 B.C.E.) believed that everything was related to mathematics, and that numbers were the ultimate reality. Isaac Newton (1642–1727) thought that God used mathematics to design the world.

Mathematics is the science of structure, order, and relation that originated from the elemental practices of measuring, counting, and describing the shapes of objects. It is concerned with logical reasoning and quantitative calculation, and it has developed increasingly along the lines of abstraction and idealization.

Mathematics As the Basis of the Physical Sciences

Since the 17th century, mathematics has been an indispensable tool for the physical sciences and technology. Seventeenth-century mathematician Pierre de Fermat is often considered the founder of the modern theory of numbers. He also discovered the fundamental principle of analytic geometry and devised methods for finding tangents to curves along with their maximum and minimum points—a methodology which provided the backbone for differential calculus.

Another early mathematician, Christiaan Huygens (born 1629) started what we now think of as mathematics in its modern form by introducing us to the first probability theory. He also founded the wave theory of light, discovered the rings of Saturn, and contributed to the science of dynamics.

His influential work of 1654, *De Circulie Magnitudine Inventa*, helped to establish his growing reputation as an influential European mathematician. A later work of 1673 postulated, similarly to Fermat, a theory on the mathematics of curvatures. He also offered complete solutions to the problems of dynamics, having based his theory on a formula that measured the oscillation of a pendulum and the oscillation of a body about a static axis.

Algebraic Theory

Early 19th-century German mathematician Carl Friedrich Gauss was a pioneering mathematician both in his native Germany and abroad. His major mathematical publication was considered the first systematic textbook on algebraic number theory.

In *Disquisitiones Arithmeticae*, he gave an account of modular arithmetic, quadratic polynomials, and a theory of factorization. This book contained natural generalizations that led to the development of number theory, setting its agenda for much of the 19th century. He set forward a fundamental theorem of algebra, which stated that every polynomial equation with real or complex coefficients has as many roots as its degree (the highest power of the variable). He reached his conclusion mainly by critiquing earlier attempts to provide this proof.

Gauss later published further works on number theory, the mathematical theory of map construction, and other varied subjects. Gauss and French mathematician and astronomer Pierre-Simon Laplace (1749–1827) also worked together to develop the mathematical theory of statistics, which looked at statistics as it related to insurance and governmental accounting procedures. Mathematical statistics would not become a recognized mathematical discipline until the first part of the 20th century.

Mathematical Logic

The start of the 20th century was marked by a shift toward abstract thinking and generalization in mathematics, where notions of *self-evident* truths were largely discarded in favor of a move toward logical concepts such as *completeness* and *consistency*. The early part of the century saw the rise in mathematical logic which built on the advances made earlier by Gottlob Frege.

Austrian mathematician Kurt Gödel (1906–1978), however, soon endeavored to put severe constraints on what could and could not be solved in mathematics. His famous incompleteness theorems stated that in any reasonable mathematical system there will always be *true* statements that cannot be proved.

The Beginnings of Artificial Intelligence

Alan Turing (1912–1954) spent many years trying to clarify and simplify Gödel's proof, something which led him to conclusions which many saw as even more devastating than Gödel's. It conjectured that some purely mathematical questions are undecidable—that there is no one algorithm that can, infallibly, give a correct *yes* or *no* answer to each instance of a problem. He posited that there is no general method which can tell us whether a given formula U is provable in K .

A spin-off of this work led to the development of the first computers and considerations of concepts such as artificial intelligence (AI).

Game Theory

Following World War II, after the deliberate destruction of mathematics in Germany and Austria by the Nazis, the focus of mathematics moved to America and in particular to Princeton. Some of the brightest mathematical brains of the century could be found here, including John von Neumann and Albert Einstein. Von Neumann (1903–1957) made vast advances in quantum theory and played a significant role in the development of nuclear physics. He is also remembered for being an early pioneer of game theory.

Number Theory

Andre Weil (1906–1998) was another war refugee to Princeton who is noted for his theorems which allowed connections to be made between algebra, number theory, geometry, and topology. Alexander Grothendieck (1928–2014) was a protégé of Weil, a structuralist who became interested in the hidden structures within mathematics. He created a new language, which enabled mathematical structures to be seen in a new light, allowing for new solutions in number theory and geometry. This was termed the *theory of schemes*.

Paul Erdős was another inspirational 20th-century mathematician who worked on the problems of number theory, set theory, graph theory, and probability theory. The 20th century also saw the complex field of dynamics—an area first developed

by two French mathematicians, Pierre Fatou and Gaston Julia—receive significant attention.

Beginning of Mathematical Sciences

By the mid-20th century, mathematics had broadened its horizons to encompass the rising class of mathematical sciences and engineering disciplines, including systems engineering and operations research. These sciences relied on research in electrical engineering and benefited from the emergence of electrical computing. This in turn brought about information theory, numerical analysis (also known as *scientific computing*), and theoretical computer science. Theoretical computer science was also semi-reliant on mathematical logic and the theory of computation. These fields have seen mathematics become a major profession involving thousands of jobs.

Statistics and Probability

Pierre-Simon Laplace, mentioned earlier, was a French mathematician and astronomer whose work was pivotal to the development of mathematical astronomy. His early work in the 1770s on differential equations and work on the philosophical concepts of probability and statistics were groundbreaking. His paper "*Memoire Sur la Probabilité des cause par les Événements*" was published in 1774, in which Laplace indicated that probability was crucial to repairing defects in knowledge.

Laplace regarded analysis as a means for attacking physical problems, a belief that spurred him on to develop the *necessary analysis* theory. For Laplace, the results of an argument could be considered true without recourse to the steps which led to this conclusion. Solutions arrived at by any means would do, so long as they were true.

The German mathematician and philosopher Gottlob Frege's 1812 publication *Theorie analytique des Probabilités* was an important milestone in statistical theory. And in 1819, he published an account of his work on probability. This involved devising a method of estimating the ratio of the number of favorable cases compared to the whole

number of possible cases. His theory involved treating the successive values of any function as the coefficients in the expansion of another function, in reference to an alternative variable. This creates a probability-generating function.

The methods devised by Laplace, working in conjunction with Gauss, led to a normal probability distribution called the *Laplace–Gauss distribution*. Probability theory was in fact to become one of his life’s endeavors as illustrated in one of his well-known formulas, the *rule of succession*, where one trial has two possible outcomes: *success* and *failure*. If we assume that little or nothing is known a priori about the relative possible outcomes, Laplace’s formula determined the probability that the next trial would be a success.

$$\text{Probability that the next outcome is a success} = \frac{s + 1}{n + 2},$$

where s is the number of previously observed successes and n is the total number of observed trials. Using this formula Laplace calculated that the probability of the sun rising the next morning, given that it had never failed to in the past, was

$$\text{Probability that the next outcome is a success} = \frac{d + 1}{d + 2},$$

where d is the number of times the sun has risen in the past. The result has been derided as absurd, with some authors concluding that the rule has no meaningful use. Laplace’s other developments in pure and applied mathematics included discussion of the theory of determinants and proof that every equation of an even degree must have at least one quadratic factor. He also performed notable achievements in the areas of fractions, probabilities, and definite integrals.

Algorithms and Data Structures

Formal algorithms have existed for millennia, for example, Euclid’s algorithm for finding the greatest common divisor of two numbers, an algorithm that is still used today in computation. It was not until 1935, however, that Alan Turing, Stephen Kleene, and Alonzo Church formulated the term *algorithm* for computational purposes.

Algorithms are computable steps required to achieve a desired result and are particularly suited to computers because they can be computationally processed. Algorithms often rely on external information that is transformed into data and arranged into *data structures*. Computational theory, which started with Alan Turing, regards some problems as beyond the ability of a machine to process efficiently, which means that computer science needs to deal heavily in math, logic, and philosophy.

Information theory was included as a new discipline in 1948 with a mathematical theory of communication put forward by Claude Shannon (1916–2001) in his paper “A Mathematical Theory of Communication,” which proposed binary digits for coding information.

Shannon stated that all information has a *source rate* that can be measured in bits per second. Information theory is a communication theory devoted to the problems of coding. It is unique in its use of numerical measure of the amount of information gained when the content of a message is learned. The theory relies heavily on the mathematical science of probability and is often applied to other probabilistic studies, including random noise and signal detection.

Emergence of Neuroscience

The Canadian psychologist Donald Hebb (1904–1985) introduced the mathematical model of learning in the brain, which was an attempt to understand the function of neurons contributing to psychological processes. His *Organization of Behavior* is considered his most significant contribution to the world of neuroscience and is where he connected the biological function of the brain as an organ together with the higher function of the mind. This was based on earlier research done by Hans Berger, who had cast doubt on the Pavlovian model of perception on response after new evidence appeared to show that the brain exhibited activity even when there was little stimulus. *Hebbian* learning is said to follow the following model:

If an axon of a cell (A) is close enough to excite cell B, and is repeatedly or persistently firing it, a metabolic change will be actioned in one or both

cells. This means that A's efficiency as one of the cells firing B will increase.

In other words, neurons that *fire together wire together*, commonly referred to as *Hebb's law*. The combination of neurons making up a processing unit are termed *cell assemblies*, their connections together making up the ever-changing algorithms that dictate the response of the brain to stimuli. This not only opened up a model for the working of the mind, in terms of the processing of stimuli, but also paved the way for the creation of computational machines that could mimic the biological processes of a living nervous system. Despite that fact that this form of synaptic transmission was later found to be chemical, modern artificial neural networks are still today based on the transmission of signals via electrical impulses.

Following the work of Hebb came the fields of neural networks and parallel distributed processing. In the early 1970s, Stephen Cook and Leonid Levin proved the existence of practically complete *nondeterministic polynomial time* problems, a revelation in computational complexity theory.

Foundations of Logic

Along with mathematics, formal logic is one of the oldest sciences in the realm of formal sciences. It was used explicitly to analyze methods of reasoning in India from 600 B.C.E., China in 500 B.C.E., and Greece between the 4th- and 1st-century B.C.E. Logic was given a sophisticated makeover by the Greeks and in particular by Aristotle in Aristotelian logic. Subsequently, logic was taken further by Islamic logicians and Indian philosophers.

The term *logic* originated from the Greek word *logos*, which can mean *sentence*, *discourse*, *reason*, or *rule*. Logic is the use and study of valid reasoning and features prominently in the subjects of mathematics, philosophy, and computer science.

First established as a formal discipline by Aristotle, the study of logic was one of the classical trivium, which also included rhetoric and grammar. Aristotle's system of syllogistic logic remained predominant in the West until the mid-19th century, when interest in the foundations of

mathematics led to the development of symbolic logic, now termed *mathematical logic*.

Aristotle's works on logic were later grouped under the name *Organon* or *instrument*. Aristotle, however, used the term to represent verbal reasoning.

Aristotelian logic posited that notions in isolation cannot express truth or falsehood. It is only when they are combined in a proposition or combination of words in rational speech that their truth or falsity can be determined. All Aristotelian logic revolves around a single notion: *deduction* (syllogism). A deduction equates to a modern notion of logical consequence: *X* must, of necessity, result from *Y* and *Z* if *X* cannot be false when *Y* and *Z* are true. This is also a definition of *valid argument*. Syllogisms are structures of sentences which can be meaningfully called *true* or *false*.

According to Aristotle, every such sentence must have the same structure and contain a subject and a predicate and must either affirm or deny a single predicate of a single subject. A classic example is his syllogism is

All men are mortal. Socrates is a man. Therefore Socrates is mortal.

So long as the premises are true, the conclusion will be too.

Aristotle's logic is a kind of *formal* logic, which as previously stated involves an inference that applies to a wholly abstract rule (i.e., a rule that is not about any particular thing or property). It involves arguments having the form of sentences of formal grammar set out in a logical language so that its content can be used in formal inference.

Because indicative sentences of ordinary language have a wide variety of form and complexity, Aristotle's formal logic requires us to ignore those features that are irrelevant to logic, replacing conjunctions such as *but* with logical conjunctions such as *and*. It also requires us to replace ambiguous expressions such as *any* with standard logical expressions such as *all*. There also needs to be recourse to schematic letters; for example, "all A's are B's" illustrates the logical form common to the sentences "all men are mortals," and so on.

Aristotle used variable letters to represent inferences in *Prior Analytics*.

Necessity in Logic

The principles of logic are noncontingent and do not depend on any particular accidental features of the world. Physics and other sciences investigate how the world is. Physicists may tell us that no signal can travel faster than the speed of light, but if the laws of physics were different this might not have been true. Similarly, biologists study how dolphins behave, but if the course of evolution had been different dolphins might not even have existed. Empirical science is contingent on how things are or could have been.

The principles of logic, on the other hand, depend only on reason, and their validity does not depend on any contingent features of the world. If p , then p is necessarily true. “If it is raining, then it is raining” is true. This is true even if it isn’t actually raining. Even if the laws of physics change, this is still true.

Formal logic is concerned with formal systems of logic especially constructed for carrying out proofs where language and rules are clearly defined. *Sentential logic* (also known as *propositional logic*) and *predicate logic* are both examples of formal systems of logic.

There are many reasons for studying formal logic: First, it helps us identify patterns of good reasoning and patterns of bad reasoning. Second, it can help with critical thinking. Formal systems of logic are also used by linguists to study natural languages.

Computer scientists employ formal systems of logic in research relating to AI. Finally, philosophers like to use formal logic when dealing with difficult philosophical problems, in order to make their reasoning explicit and precise.

Deductive Reasoning and Inductive Reasoning

Deductive reasoning is concerned with what necessarily follows from given premises (if a then b). *Inductive* reasoning is the process of deriving a reliable generalization from observations and is sometimes included in the study of logic. *Validity* is another important point: An inference is deductively valid *if and only if* no possible situation exists in which the premises are true but the conclusion is false.

Inductive arguments, however, are neither valid nor invalid, since their premises allow only for a probability of certainty, without concluding anything. While the notion of deductive validity can be stated for systems of logic in terms of semantics, inductive validity requires sets of observations, some less formal than others. These can use mathematical models of probability.

Logical systems must be consistent; theorems within a system cannot contradict one another. They must also be valid in that the system’s rules of proof never allow for a false inference from the premises. Logical systems must have the property of *soundness*, which is only possible if the inference rules prove only formulas that are valid semantically. In general, this means having the property of *truth*—although this is not always the case.

An argument can be said to be sound only if the argument is valid and all of the premises are true. For example, “All men are mortal,” “Socrates is a man,” and “Therefore Socrates is mortal.” This is a valid argument because the conclusion is true, based on the premises; in other words, the conclusion follows from the premises, and since the premises are in fact true, the argument is sound.

A logical system must be *complete*, meaning that if the formula is true, it can be proven (if it is true, it is a theorem of the system). Although most logical systems possess these properties, not all of them do.

Jan Łukasiewicz, a Polish logician, stated that the introduction of variables was one of Aristotle’s greatest inventions. According to Aristotelian logic, only the logical principles stated in schematic terms belong to logic—not the concrete examples. For instance, the concrete terms *man* and *mortal* are analogous to the substitution values of the placeholders A, B, C—termed the *matter* of the inference.

Along with the Aristotelean syllogism, modern symbolic logic is an example of formal logic. Symbolic logic is the study of symbolic abstractions that capture the formal features of logical inference. It is often divided into two branches, *propositional logic* and *predicate logic*. Mathematical logic is an extension of symbolic logic and particularly applies to the study of model theory, set theory, proof theory, and recursion theory.

In 1854, the English mathematician George Boole published *An Investigation of the Laws of*

Thought on Which are Founded the Mathematical Theories of Logic and Possibilities, which introduced the principles of symbolic logic and what is now referred to as *Boolean logic*. Boolean logic is a complete system for logical operations.

Today it has many applications in computer technology and forms the basis of digital electronics. It involves a system of algebra in which all values are reduced to either true or false, and it is these true/false rules that govern the foundation of all electronic circuits in a computer. Just as *add*, *subtract*, *multiply*, and *divide* are the primary operations of arithmetic, so *and*, *or*, and *not* are the primary operations of Boolean logic.

Often considered the founder of modern logic and of analytic philosophy, Gottlob Frege, mentioned earlier in this entry, found the language of Boole unsuitable for being too unambiguous. For Frege, Boole's logic, which was divided into primary and secondary logic, was unable to deal adequately with multiple generalities. Frege found the method of analyzing propositions in terms of subjects and predicate concepts imprecise and antiquated. He replaced subject/predicate with the notions of *function* and *argument* and defined a *concept* as a function that has a truth value, with true or false as its value for any object as argument. His logic was based on axioms, beginning with a fixed number of axioms from which all other logical truths could be derived.

In 1869, Frege published *Begriffsschrift* (*concept-script*), which put forth quantifier notation. This predated modern predicate logic by dealing with quantifiers using variable bindings. Frege attempted to show that all basic arithmetic truths can be derived from purely logical axioms. In his *Basic Laws of Arithmetic, volume I*, he presented a new logical language. In his paper "A Logical Inquiry," first published in 1918, Frege saw logic as the means to discover the laws of *truth* itself, whereas discovering different truths is the task of all the sciences.

Frege was to play a crucial role in the development of modern logic and analytic philosophy. His work in logic is often seen as the representation of a fundamental break between contemporary approaches and the older Aristotelian tradition. He invented modern quantificational logic and created the first fully axiomatic system for logic that was complete in its treatment of propositional

and first-order logic. When it came to mathematical logic, he was a proponent of the thesis that mathematical truths are logical truths. His distinction between sense and reference of linguistic expressions was groundbreaking in the work of semantics and language, profoundly influencing thinkers such as Bertrand Russell, Rudolf Carnap, and Ludwig Wittgenstein.

Rival Conceptions of Logic

Logic arose from efforts to achieve correctness in argumentation. Some logicians, however, believe that logic should only be concerned with the right forms of inference. The American philosopher Thomas Hofweber believes that logic should not cover good reasoning as a whole; that should be the job of rationality. It should instead deal with inferences whose validity can be traced back to formal features of the representations involved in inference, whether mental, linguistic, or otherwise.

Informal logic looks at natural language arguments and the study of fallacies, Plato's dialogues being good examples. Informal logic is used to mean the same thing as critical thinking and sometimes refer to the study of reasoning and fallacies in everyday life.

The Importance of the Formal Sciences

Formal sciences are essential to the sciences in general. Mathematics in particular plays a crucial role in the expression of scientific models. Observing and collecting measurements, as well as predicting and hypothesizing, usually require extensive use of mathematics. Arithmetic, geometry, algebra, trigonometry, and calculus are all, for example, essential to physics.

Virtually all branches of mathematics have applications in science, including in so-called pure areas of number theory and topology. Statistical methods, which comprise mathematical techniques for summarizing and analyzing data, enable scientists to assess levels of reliability and range of variation in experiments. Statistical analysis also plays a major role in the natural and social sciences.

The formal computational sciences enable us to gain a better understanding of scientific problems, better even than mathematics alone. In fact, according to the Society for Industrial and Applied

Mathematics, computation is nowadays as important as experiment and theory for advancing our knowledge of science. The theorems and formulas obtained by logical means that presume axiomatic systems, rather than the combination of empirical observation and logical reasoning, has become known as the *scientific method*.

Major advances in formal science have often led to major advances in the empirical sciences. The formal sciences are essential in the formation of hypotheses, theories, and laws and help us to discover how things work, how people think and act.

FRAMEWORK

A framework is an abstract logical structure of meaning that guides the development of a study enabling a researcher to link their findings to a body of knowledge. A *theoretical framework* concerns a framework of study that is based on a theory. A *conceptual framework* is a term used in a study that has its roots in a specified conceptual model.

A conceptual framework requires that a researcher uses concepts from the available literature to establish evidence to support the need for a certain research question. If these links have already been established through valid research, this ready-made theoretical framework can be used as a map to help guide other scientists with their own research questions.

Theoretical frameworks provide a perspective through which it is possible to examine a topic. There are no right or wrong theoretical frameworks, since a topic can be looked at from multiple perspectives. Frameworks are there to guide research, determine which things should be measured, and define what kinds of statistical relationships one should be alert for.

Theoretical frameworks are critical in deductive, theory-testing types of study. They consist of interrelated concepts, together with their definitions, along with existing theories that are used for a particular study. Frameworks need to express an understanding of the theories and topics relevant to the topic of research and relate them to broader fields of knowledge.

Frameworks are not *off the peg* or readily available in the literature, since they must be applied to the case at hand.

A theoretical framework strengthens a research study in the following ways:

- It provides an explicit statement of theoretical assumptions which permit the reader to critically evaluate them.
- It connects the researcher to the existing knowledge and guides them with a relevant theory. This provides a basis for the hypothesis and choice of research methods.
- It articulates the theoretical assumptions of research study, forcing researchers to address *why* and *how* questions. Theoretical frameworks allow for us to move from simply *describing*

observed situations or phenomena to generalizing various aspects of a phenomenon or occurrence.

- Having a structure helps to apply limits to those generalizations. A theoretical framework identifies the key variables that influence a phenomenon, encouraging examination of how those variables might differ and under what circumstances.
- Frameworks are useful organizing devices in empirical research. A conceptual framework can be applied to deductive, empirical research at micro- or individual-level study.

Conceptual Frameworks

Conceptual frameworks can be thought of as abstract representations connected to the goal of the research project. Patricia Shields and Nandhini Rangarajan use American football play as a good metaphor for a conceptual framework. They define a conceptual framework as the way ideas are organized to achieve an objective. Football play, like a conceptual framework, is of course connected to a purpose. In American football, a play is a strategy or on-the-ground plan of action used to move the ball down the field. A *play* occurs at kickoff or a *snap* during a down, and plays can be basic or complex. The components of a play are subdivided into many smaller parts, just as the parts of a framework should be divided into smaller aspects.

According to Shields and Rangarajan, empirical inquiry is akin to coaching football and inventing plays. Researchers should see themselves as coaches who need to develop frameworks (plays) as they work through their literature and define research objectives. Shields and Rangarajan introduce five main types of conceptual frameworks designed to bring coherence to all aspects of the research process. Each conceptual framework is defined to match a specific research purpose. The five frameworks are *working hypotheses*, *categories*, *practical ideal type*, *models of operations research*, and *formal hypotheses*.

Working Hypotheses: Used for Exploratory Research

A working hypothesis is a hypothesis that has been provisionally accepted as a basis for further research. In using a working hypothesis, it is hoped that even if the hypothesis fails, a tenable

theory may be produced. Like all hypotheses, a working hypothesis is constructed in terms of explanations that can be linked to the explanatory research. Charles Sanders Peirce (1839–1914) set forth his belief that an explanatory hypothesis is useful not only for the tentative conclusion it entails but also as a starting point for further research. This idea of justifying a hypothesis as worthy at the research level, not just for its use as a logical conclusion, is central to the notion of a working hypothesis. This notion was later elaborated by pragmatist John Dewey (1859–1952).

Categories: Used for Descriptive Research

Descriptive research relates to the characteristics of a phenomenon under study. It does not answer “why?” “when?” or “how?” the characteristics have occurred but rather answers the “what?” question; namely, what are the characteristics of the phenomenon being studied? These characteristics generally make up a kind of categorical scheme also known as *descriptive categories*. An example we could use is that of the periodic table, which categorizes the elements. Scientists have used their knowledge of the characteristics of protons, electrons, and neutrons to create this categorical scheme. We now take this scheme (the periodic table) for granted; however, it was originally based on descriptive research. Descriptive research tends to precede explanatory research—as illustrated in the fact that scientists use the descriptive elements of the periodic table to explain chemical reactions and make predictions about what will happen when elements are combined.

Practical Ideal Type: Used for Gauging

A practical ideal conceptual framework involves that there be a set of criteria suitable for judging a program process or activity. These criteria can help to determine best practices. The term *practical* relates to the idea type because the model is subject to revision.

Models of Operations Research: For Use in Decision-Making

Mathematical models and equations and computer models are often used to describe the past behavior of a process and predict the future path

of a process within the boundaries of the model. In certain cases, the probability of an outcome rather than its specific outcome will be predicted, as in much of quantum physics. The goal of operations research is to provide a framework for constructing models of decision-making problems, find the best solutions, and implement those solutions in an effort to solve the problems. The *problem* is the occurrence or situation that warrants enquiry. The decision maker is the individual or group responsible for making decisions regarding its solution. The problem may be abstract or real and may involve current operations or proposed operations.

Formal Hypotheses: For Use in Explaining and Predicting

A formal hypothesis consists of concepts that can be connected, and their relationship tested. Numerous hypotheses amalgamate to form a conceptual framework. When sufficient data and evidence are gathered to support a hypothesis, it becomes a working hypothesis. Proposing a formal hypothesis is an extremely important part of the research project, since the thesis or study is at the mercy of the hypothesis.

Explanation is the most common type of research purpose in empirical research. The formal hypothesis is the framework associated with explanation. Explanatory research generally focuses on *why* a phenomenon has been caused to happen. Formal hypotheses provide possible explanations in answer to the questions that are tested by collecting data and then assessing the evidence, which is usually quantitative via statistical testing. An example of this could be where a researcher wishes to determine the factors contributing to house fires in American cities. Three factors may be put forward as possible influences on residential fires: population, building makeup, and the environment. These factors would become the conceptual framework they used to achieve the research goals to explain the influences of residential fires in U.S. cities.

A *prediction* is a forecast or statement about the way things will happen in the future, usually, although not always, based on experience or knowledge. A prediction is more specific than a forecast since it makes a statement about what

may happen or what is expected to happen, while a forecast may cover a range of possible outcomes. Predictions are useful when making plans about possible developments. More formal predictions can be made by testing formal hypotheses using statistical methods. Formal hypotheses are created by connecting systematic knowledge of an area giving clear reasons why the predicted relationship might exist. Predictive inference is part of statistical inference. Established science makes useful predictions that can be highly accurate. New theories allow for predictions which can be disproved if they are not borne out. Scientific predictions are rigorous and generally quantitative statements forecasting what will happen under certain conditions. For example, if an apple falls from a tree it will be pulled toward the center of the earth by gravity and will do so according to the specified and constant acceleration. Scientific method is built on testing statements that are logical consequences of scientific theories. This is done through observation and experiment.

These conceptual frameworks, as put forward by Shield and Rangarajan, are not exhaustive, as they themselves point out. Such frameworks may not be applicable for inductive forms of empirical research, either. They merely provide a useful point of departure for those new to research when setting out their own research design.

Frameworks Provide a Lens

Frameworks are important in explanatory studies where about the areas to be researched are unknown beforehand. Frameworks are especially helpful in these instances because, even if not much is known about a topic and no matter how unbiased the position we *feel* we are taking, it is difficult not to have preconceived notions—even a very general preconceived notion about the subject we are about to tackle. If, for example, a researcher has a fundamental view about how people in general behave (perhaps they has an inclination to think they are lazy and unhelpful), this may cause bias when researching a topic that involves human nature. This researcher may fail to notice things that don't fit in with this preconceived framework. By making a framework explicit at the start, other frameworks can be tried

out to see the organizational situation through a different lens.

Isaiah Berlin (1909–1997) believed that philosophers and authors view the world either from a fox’s point of view or from a hedgehog’s—two types of animals he used to describe the different ways in which we see the world. They are a way of describing the analytical tools, or conceptual frameworks, we each use to make conceptual distinctions and organize ideas. According to Berlin, the philosopher Plato, the playwright Henrik Ibsen, and the novelist Fyodor Dostoevsky were *hedgehogs*, or types of people who view the world in terms of a single idea. Foxes, on the other hand, according to Berlin, incorporate a pluralistic view of the world, in that they draw on a variety of experiences. Rather than pinning things down to a single idea, they see it through multiple, sometimes conflicting lenses. He regarded Aristotle, Shakespeare, and the novelist James Joyce as being in this category. Berlin took the title of his essay “The Hedgehog and the Fox” from a reference to an ancient poetical work by Archilochus, who describes the fox as knowing many little things, while the hedgehog knows just one big thing. Our individual conceptual framework is based on our beliefs, experiences, and knowledge. A theoretical framework helps researchers to understand and overcome their personal biases so they can gain better insight into their results. They can also learn to use other frameworks during the course of their study; for example, they could learn to stage their research from more of a fox’s or more of a hedgehog’s type of view.

Types of Research

Frameworks are useful in both applied and basic research, applied research being designed to solve a particular problem in a particular circumstance. Applied research refers to scientific study and research that seeks to solve a practical problem. This could include efforts to find solutions to everyday problems and develop new technologies. Applied research generally employs empirical methodologies.

Frameworks are also important for basic or *pure* research, which is designed to find the principles that underlie certain situations. Basic

research involves discussion about ideals, programs, and methodologies.

Frameworks have also been used to good effect in conflict theory, allowing for a way to determine the balance required to reach a resolution. Within conflict frameworks, both visible and invisible variables are at play, with both parties having a subjective viewpoint. Adopting frameworks allows us to focus on specific variables and define an objective framework that the research will take in analyzing and interpreting the data to be gathered. It allows us to build knowledge by validating or challenging theoretical assumptions, thus enabling us to take a practical approach to conflict resolution, for example. Mediation is built upon a commitment to developing conflict resolution skills both individually and collectively, in order to develop equitable relationships. The development of these skills requires an acceptance of plurality or an agreement that there are a variety of possible ways to determine both the process and outcome of dispute resolution. That there are potentially a number of valid points of view poses a fundamental challenge at the philosophical level to established assumptions and increases the likelihood of an agreement.

How to Develop a Framework

First, we need to examine the research problem, since this anchors the entire study and forms the basis of the framework.

Next is to brainstorm the key variables in the research and answer the question: What factors contribute to the presumed effect?

A review of related literature should then be undertaken to find answers to the research question.

The next step is to list the constructs and variables that might impact the study and group them into independent and dependent categories.

Finally, a researcher should review key theories and choose the theory or theories that best explain the relationships between the key variables. The final step is to discuss the assumptions used to limit the scope of the relevant data.

GAME THEORY

Game theory is a mathematical system of reasoning, referring to cases where two or more decision-making agents with a set of preferences associated with the various possible outcomes participate in a process. The actions of each intervenient are critically affected by the decisions made by the other/s, and the final result depends on the totality of strategies adopted. Each game is characterized by a set of information available to participants, a predetermined number of rules that limit the strategic choices of decision makers, and a range of possible outcomes or *payoffs*. In broad terms, it may be said that game theory is based on the notion that people's choices are a result of well-defined preferences and an analysis of the relationship between their own choices and the decisions of others. Given this profile, game theory is a tool of high analytical potential regarding situations of conflict and cooperation based on strategic behavior, specifically referring the ways how people interact and decide. By studying the strategic behavior of agents, it is possible to sketch answers to questions regarding what is decisive for the existence of cooperation between the parties or when it is rationally more beneficial to compete.

The Theory

Generically, game theory models operate on the basis of concepts related to *rational choice theory*, with decision makers taking the course of action

considered the most suitable according to a certain preference scale and choices being made without any fundamental qualitative restrictions. Various types of strategies are identifiable. The *dominant strategy*, so called, occurs when a course of action is possible, better than any other for one single player, regardless of the actions of others. A *pure strategy* exists when it is possible to outline the moves that a player will make when facing some situation. A *mixed strategy* corresponds to assigning one probability to each possible pure strategy in the game. The variety of strategy named *max-min* posits players adopting a cautious stance and seeking to obtain the least negative of a group of poor results. The *tit-for-tat* strategy refers to a replicative-retaliatory attitude by players: Initially, the player cooperates, analyzes the behavior of others, and subsequently tends to reciprocate their actions. In the *grim-trigger strategy*, the player also cooperates the first time and insofar as the remaining players continue to collaborate, but if one of the others fails to cooperate, this is deemed sufficient cause for giving up and abandoning cooperation. Other noteworthy strategies are *collusion*, when there is an agreement between certain elements in order to deceive others and gain advantages in the game; *backwards induction*, when, starting from the end of the game, the player considers the different options and outcomes in order to determine the optimal sequence of actions; *forward induction*, when it is assumed that past strategies have been chosen rationally by several players and, following its analysis, it typifies the behavior of each one with a view to predicting

their future actions; and *Markov strategy*, when players proceed based only on descriptions that summarize the history of the game.

One classical problem of game theory, referred to as the *prisoner's dilemma*, remains a key analytical tool, capable of displaying how two individuals may rationally decide not to cooperate, even though circumstances presumably would tend to make cooperation advantageous for both. Initially suggested by Merrill Flood and Melvin Dresher in 1950, this dilemma was later formalized by Albert W. Tucker, who named the device exemplifying with the theme of imprisonment. Two prisoners accused of the same crime are kept separate, and each is given the option to confess. The authorities lack sufficient evidence to accuse them and hence are dependent on their testimonies. If neither one confesses, both will be given a sentence of 2 years. If both confess, they incur a sentence of 6 years. If only one of them confesses, he or she who does is released while the other will have an extended sentence of 10 years. Considering this situation closer we verify that, although each individual prisoner has advantage to confess (penalty of 0 or 6 years for confession, versus respectively 2 or 10 for nonconfession), joint nonconfession is the best option for the pair of players: penalty of 2 years each, instead of 6 each for joint confession. Notice that the best option is unstable, given the uncertainty for each party regarding the cooperativeness of the other. By contrast, a situation of mutual noncooperation corresponds to the so-called *Nash equilibrium*: No player can improve his or her outcome by unilaterally changing strategy, in spite of the existence of a better solution for both parties. However, it is not obtainable by simply acting otherwise because the improved results crucially depend also on changes in the behavior of other agents. Therefore, the problem basically consists in how to avoid falling into situations of generalized noncooperation, which subsequently become almost impossible to leave behind.

History

Some of the core ideas of game theory are identifiable as early as the 18th and early 19th centuries, in the works of James Waldegrave (1684–1741) and Augustin Cournot (1801–1877), but the

decisive developments occurred during the first two decades of the 20th century, with the works of Ernst Zermelo (1871–1953), Émile Borel (1871–1956), and John von Neumann (1903–1957). Von Neumann's first publication concerning games, in 1928, sought to demonstrate that in finite zero-sum games—that is, when the gain of one player corresponds to the loss of another—the solution for mixed strategies exists and may be obtained by applying mathematical techniques. In 1937, von Neumann presented a new model, this time based on Luitzen Egbertus Jan Brouwer's *fixed-point theorem* (presented in 1910); and in 1944, with *Theory of Games and Economic Behavior* by John von Neumann and Oskar Morgenstern, game theory acquired the status of a field of studies, extending its scope of influence to applied mathematics and economics. The mathematician John Nash (b. 1928) published in 1950 a series of articles in which he defined the concepts that became known as *Nash equilibrium* and the *bargaining problem*, giving renewed momentum to game theory, whose models started to be used in political science, economics, and psychology. Nash distinguished two types of games: cooperative ones, in which decision makers can combine in order to achieve a more favorable solution, and noncooperative games where the players' personal incentives prevail, leading to a less-than-excellent result that still configures a stable situation. According to the theorem of Nash equilibrium, participants seek a set of alternatives whereby everyone may be benefited by his or her strategy. Taking the competition as assumption, von Neumann concentrated its approach in zero-sum games, positing that even matches involving several people are analytically reducible to multiple sets of two. In turn, Nash chose to introduce the cooperative element, considering that through cooperation, individual gains may be maximized, and therefore, in the strategic analysis of the game, participants must take into account both the individual and collective perspectives.

Game theory has been applied extensively since the 1940s. Initially, it was used essentially for military purposes, notably in World War II, the Cold War, and the Korean War, application in other domains quickly followed, including physics, zoology, and social sciences. Indeed, Richard Dawkins (b. 1941) has importantly shown that

game theory is usable in studying some of the behavior patterns of genes in the evolution of species: In some cases, genes that cooperate evolve, obtaining higher individual gain. Since the 1970s, game theory is also used as an instrument of evolutionary biology, and its theoretical methods became very important in microeconomic theory as well, with the Nobel Prize in 1994 being awarded to three game theorists: John C. Harsanyi (1920–2000), who focused on situations where some decision makers have inside information as to important aspects of the game, corresponding to the so-called model of incomplete information; John F. Nash and Reinhard Selten (b. 1930), who in 1965 provided more in-depth knowledge of equilibrium, with the introduction of the concept of *subgame perfect equilibrium*. Nash identified three modes of application of game theory: economics, aiming at choosing one option based on the calculations of probability and maximization of utility; psychological, which by highlighting notions of incomplete information and expected utility emphasize the critical nature of intentions and expectations of the various participants; and finally the sociological mode, understanding the decisions taken by analyzing previous situations. Game theory application to economics should, however, be added with an important proviso: Its model of reasoning assumes a *strategic rationality*, whereby the conduct of each agent partially shapes the environment faced the others (and reciprocally), whereas economics' model of perfect-competition markets instead posits a simpler *parametric rationality*, each agent's conduct fundamentally irrelevant to the design of the environment faced by all of them.

Three successive generations are also identifiable in the approach to game theory: von Neumann and Morgenstern laid the foundations of the theory that aimed to be a tool for rationality analysis, referring to contexts in which the actions of the various decision makers are conditioned by expectations of possible reactions. Starting from the idea that policymakers adopt actions they rationally identify as more advantageous to themselves, the analysis of aspects such as the consequences of the available options, or the possible existence of alliances between players, was understood as a way of deduction of optimal strategies for each hypothesis. The second generation was led by Omar Khayyam Moore and Alan Ross

Anderson, who introduced one psychological component in the behavior of decision makers, leading to the concept of *subjective probabilities*: Players may not be fully informed, and so expected utility (both in terms of intent and of expectations) for each dimension plays a very important role. Robert Aumann (b. 1930) presented in 1987 what is considered the third approach, based on a combination of logical and subjective probabilities of players. According to Aumann, given that policy makers may adopt nonoptimal strategies, there is an undetermined number of possible solutions for each game, which implies introducing the notion of risk and calculating the probabilities of various outcomes. Aumann and Thomas Schelling (b. 1921) were awarded the 2005 Nobel Prize in Economics for their use of game theory in strategic analysis of international conflict resolution. Schelling pioneered the use of game theory with this purpose, including a group of studies on the nuclear arms race during the cold war. He presented concepts such as *conflict behavior*, *focal point*, and *credible commitment* that generically deal with various forms of subliminal and indeed mostly preconscious knowledge, but often very important regarding decision making within contexts of interaction. Credible commitment consists of a group of dispositions not strictly rational in character, yet still necessary both in order to prevent noncompliance in cooperative situations and also allowing participants to take advantage of the very plausibility that situations might evolve toward conflict, by benefiting from possible antagonists' risk-aversion.

Mention is also due to Robert Axelrod (b. 1943), who in *The Evolution of Cooperation*, published in 1984, highlighted the rule of *tit for tat*, or *pay in kind*, and posited a very efficient strategy in situations of prisoner's dilemma, containing an intuitive moral justification. His argument for the so-called evolutionary viability of *tit for tat* stresses that it verifies first of all the trait of being a very simple rule, one likely to emerge regardless of cultural components, altruistic feelings, and even the very existence of intentionality. This is indeed a decision-making algorithm originally presented by the mathematician Anatol Rapoport, implying to cooperate in principle, to retaliate whenever the interlocutor *misbehaves*—that is, doesn't cooperate—yet still to remain willing to

return to a cooperative attitude, once payback is consummated. Therefore, this is an overall *nice* (in principle cooperative) rule, *retaliatory*, yet still *forgiving* strategy. Tit for tat proved, in various tournaments of prisoner's dilemma, to be a highly successful option, besides favoring other cooperative strategies, which tended to be subject to predation by noncooperative, or *free-riding* strategies, and also inhibiting these by implying the limitation of their success: The typical tit-for-tat player is virtually impossible to deceive, which results from the defining algorithm's simplicity.

Continuing Developments

Robert Axelrod himself extracted a group of conclusions regarding the manifold and multiform implications of the reasoning just described. An important field of application is biology, where the actual fact of cooperation is usually recognized, in spite of the global frame of reasoning mostly suggesting a Darwin-inspired generalized *struggle for life*. The central question therefore concerns the very possibility of cooperation, and this theorizing is important precisely because it stresses simplicity, and so also the plausibility of emergence and subsequent viability of cooperative behaviors—assumed as unintended but a likely result of random mutations. Axelrod stresses that this variety of behavior may initially occur without any centralized decision or command order regardless of cultural devices such as moral norms, with no need for benevolence or mutual sympathy, and bottom line without any real intention of producing such cooperative result. However, he adds, those cultural devices, and psychological inclinations for *altruistic* or *benevolent* behavior indeed tend to emerge: more as a consequence of cooperation than as cause for it, although no doubt such devices do reinforce the tendency for a subsequent cooperative conduct.

In his 1997 work *The Complexity of Cooperation*, Axelrod returns to these themes, namely, assuming that the models used, the so-called *agent-based models*, which may be said to correspond to the generalization of problems typical of the *prisoner's dilemma* to n participants, have neither strictly inductive nor rigorously deductive characteristics, rather being mostly imagination-auxiliaries. Another noteworthy trait is precisely

the explicit recognition, by Axelrod, of the fact that his work had been discussed with actual policymakers, namely, people making decisions relevant for the United States's foreign policy: This interaction was not only a source of enrichment for Axelrod's assumptions but also of his theorizing's becoming susceptible of influencing the way agents proceed. In short, this is explicitly not a theory regarding *outside* reality and merely *about* it, but rather a theory whose components are quickly, directly reabsorbed by the realities studied and coming to integrate them. This induces the problem of knowing to what extent game theory itself may be, and indeed is, taken into consideration by strategic decision makers, and therefore, the question emerges of the theory's strictly *performative* validity: It may occur that it is only tenable insofar as agents become persuaded of its validity, thereafter proceeding in accordance with this belief.

Finally, a group of studies must be referred to, intimately related with the prisoner's dilemma model and also corresponding to the generalization of its reasoning scheme to situations where not just two but many people repeatedly interact. This research was developed by Robert Bowles and Herbert Gintis, who have suggested an analytic framework highlighting the importance of the so-called strong reciprocity for the preservation of cooperative strategies among large groups. Put schematically, strong reciprocity corresponds to the notion of paying-in-kind to anyone who behaves either in a cooperative or in a free-rider, *shirker* fashion. In a very large group of experimental studies, and with reference to very different cultural backgrounds of the participants, a tendency was clearly identifiable by most players to continue cooperating with others who also cooperate, but also—and very importantly—to punish trespassers, even involving a cost for the players who exercise punishment. Notwithstanding this individual cost, and so also the formal apparent irrationality of that conduct, consistent verification is obtainable that the diffuse presence of *strong reciprocators* in any given population works excellently as inhibitors of shirking practices. Given the fact that these are noxious not only for themselves, but mostly out of the bad examples they establish and the *cascade effects*, or *threshold-dependent* noncooperative behavior

they may induce, the necessary conclusion is that *strong reciprocity* is crucial to keep interactions in the cooperative track; otherwise, the predictable sequence of small-scale noncooperative events would imply the crumbling of the whole fabric of social cooperation.

Also very importantly, the fact that this is a cross-cultural phenomenon induces Bowles and Gintis to wonder about the existence of either a biological set of dispositions making most humans inclined toward this practice or alternatively a system of cultural values so generalized as to encompass practically all societies and cultures. This aspect refers also to a tendency in large groups, and again in cross-cultural experiments, to adopt conducts of *fair division* of payoffs in the so-called ultimatum games. If there is one player establishing the ratio of partition for a certain global payoff, and the other is limited to either accept the partition or reject it, thereby implying zero-gain for both intervenient parties, most people tend to spontaneously propose partitions somewhere between a 50–50 basis and, at the most, a 70–30 scheme. Moreover, when some players suggest a more imbalanced or *unfair* model (e.g., 90–10), the person who is presented with this offer does often tend to refuse it, mostly out of moral outrage, and indeed with some pleasure associated with punishing the misbehavior. One possible conclusion is that payoffs are relevant not in absolute terms but only comparatively, and therefore implying the appeal to notions of distributive justice.

GENERALIZATION

The term *generalization* is often used in the literature on research and methods when we make a theoretical claim and observe the data. But do we really observe all the data and then deduce our conclusion? Roland Barthes states that the world's narratives are numerous and further explains that all narratives share structural features. Is he suggesting a generalization that applies to narratives worldwide? Or when we reach toward meaningfulness without studying all contexts; is it generalization that supports our observations?

Generalization is a necessary component in survey and research for the formation of theories, both scientific and otherwise. But how is something generalized? For example, if the first pen I pull from my bag is green, and the second pen I take from my bag is also green, can I then generalize and say that *all* the pens in my bag are green? Is generalization more in line with inductive reasoning? It appears that the validity of one's conclusion is based on some premises, contexts, and the observer's prior experiences. This does not mean, however, that generalizing is a subjective activity.

Generalizing statements constitute the explanation schema that is the method of scientific reasoning. It is used to label many aspects of research process.

The ability to express a generalization in words presupposes a number of capacities, previously realized, for intelligently using words, phrases, and clauses that make up the sentence, but generalization is observational rather than judgmental. The generalizing claims are explicit in survey or experimental research, whereas they are less explicit in qualitative research. There are two basic groups of phenomena with which the term is ordinarily linked: The process of generalization is

a *transition* from a description of the properties of a particular object to finding and singling them out in an entire class of similar objects. Here, the researcher finds and singles out certain stable, recurring properties of these objects. For example, Chinese pronounce /r/, a trill sound, as lateral /l/, so a linguist can generalize that wherever there is a /r/ sound in a loan word, it will be pronounced as /l/ by Chinese speakers.

In marking the result of the generalizing process, the researchers' ability to abstract the findings from certain varying and particular attributes of an object is recognized. For instance, a linguistics field researcher finds out that a three-language formula has been adopted in Indian primary and secondary education. If he interviews any student studying in Grade 6, then he can generalize and deduce: "Indian students know more than one language," or "The students are multilingual." Moreover, when the researcher encounters a child having no formal education, this might make him predict "The child might not know more than one language."

During the generalizing process what takes place is as follows: First, a researcher finds a certain invariant in an array of objects and their properties, and a classification of the invariant by a description; second, the researcher finds a usage of the variant that has been cast out to allow the identification of objects in a given assortment.

Developing a generalization is regarded as one of the principal processes of constructing a concept. In texts and reference books on various subjects, the teaching material, generally, is organized, so that the learners' interaction with it will lead to the relevant generalizations. The verification of the level of generalization that the learners have reached is described in the methods manual that directs the instructors in teaching.

For instance, in the English course, there is study of the morphological structure of a word. Specifically, the learners become familiar with the root of the word, with the infinitive, prefixes, suffixes, and so on. According to their textbook, the children do the following exercise. First, they copy certain texts and they find and single out the words that have a common part in them and underline it (play, plays, played, playful, playfully, playboy, etc.). Then, they recall the instances of similar lexicon that are specifically pointed out

in the textbook. These lexicons are related in meaning; they have a common root. After this, they become familiar with the definition of stem and base: "The part of a word that is left after you remove the part that changes when forming a plural, past tense, and so on." The learners again do a series of activities on finding and grouping words that have a shared root. The whole activity is known as a generalizing process to construct a concept.

Arriving at this generalization scheme in the teaching process presupposes a variety of special conditions. Chiefly, a collection of concrete impressions or a set of particular objects is needed. They provide the raw material for making a comparison; for this, the similar, common, collectively held qualities of the objects are detected. However, the collections of raw material should contain very different variants of the combination of similar qualities and should be sufficiently diversified with concomitant attributes.

Thus, to form the generalization that determines the concept of a suffix, the sets provided for comparison should contain words having the same root with different suffixes and ones having different roots with the same suffixes, words belonging to different grammatical relations, and so forth.

The adequacy and completeness of the generalization is decided by the broadness of the variations of the attributes that are associated on the existence in the raw material of extremely unusual and unexpected combinations of the common quality with the belonging form or attributes of expression—for instance, when researchers are constructing a generalization related to the concept they see, and they construct it with highly varied correlations.

Generalization is also considered as a *rule* that is inseparably linked to the operation of abstracting. Laying out a certain quality as a shared one includes separating it from other qualities. This allows the researcher to convert the general quality into a particular and independent object of the following actions. To know what is common is the consequence of having compared and recorded the common element in an object of inquiry, which is always abstract or conceivable. The exclusive separation, the finding out what is common, and its nearness to the particular—this is

the process of abstraction. Hence, when the generalization “the number 10 is 2 more than the number 8” is being constituted, there is not only an isolation of this feature from the other properties, such as size, material, and word, but also a finding out of the similar feature that for any objects 10 is two more object than eight, as a result of which the provided relationship starts to be considered as a relationship of abstract numbers, as a specific object of attention, abstracted from concrete objects.

The Logic of Generalization

In a generalizing process, a researcher discerns a claim that what is the case in one time or place will be so elsewhere on in another time. Regular and routine social life is dependent upon the progress of subjects accomplishing this. Inductive generalization is reliable in everyday life for the purpose it allows, and it includes a great amount of incorrect inductive assumption without considering the consequences. In the social sciences, as well as in the natural sciences, the researcher aspires to more reliability, which leads to the clarification of generalization toward inductive reasoning based on axiomatic (or deductive) reasoning or probability.

The physical world, particularly at the biological level, and much of the systems of the social world are constitutionally complex and characterized by feedback mechanisms; deductive generalizations are available where invariant laws function in large-scale physical systems. In social world systems, specifically, meaningful behavior is a result of consciousness, and the same circumstances or actions can generate different subjective meanings, or, contrarily, subjects may act on the basis of similarly expressed meanings. Social critics of generalization maintain that because of this, generalization is not possible.

In qualitative research, more recognizable and probabilistic reasoning may be used under certain circumstances. This generalizing form is applied from sample to universe in survey research depending upon the form of probability sampling, through which within every case, each layer has the same known probability of selection. Other strategies, such as quota sampling and multiple captures, aim to emulate a probability sample where such

sampling is impossible. In the social world, statistical generalization that is not possible concerning the issue of variance gives way to the second class of generalization.

Independent of statistical generalization is *moderatum* (moderate) generalization. Although it is possible to express *moderatum* generalizations in formal terms, yet they look like the everyday generalizations of life in their scope and nature. They are called moderate because they are open to change and they do not make all-encompassing sociological statements. For this reason, they can never lead to axiomatic generalizations because their alteration, by its nature, makes them hypothetical. Moreover, they are testable statements that might be refuted or confirmed at later stage.

It has been observed that variables such as system, subject, and task affect performance. Statistical generalization rigorously limits the generality of the results in the research. Strict attachment to the same experimental conditions, and the same fixed levels of the independent variables, would make a research project ineffective, while a reasonable process of generalization could make a research effort more productive. Generalizations can be emulated from one type of task to a similar type of task, from one class of users to a similar class of users, and from one set of experimental conditions to a similar set of conditions. But a researcher should be cautious of generalizing results when the agent upon which research is conducted varies greatly.

The classes of users, the task, and environmental and system variables are to be considered in generalization. The user classes vary in experience (knowledge, understanding, automaticity, etc.), skills (e.g., writing, typing, clerical, motor, visual, drawing), personality (temperament, style), and motivation (excitation level, achievement). The task conditions show variation in demands (time pressure, cost of errors, etc.), definition (problem definition, types of targets, restrictions on solution, etc.), and knowledge domain (e.g., structure; concreteness, richness). The system conditions vary in input devices such as mouse and keyboard and display devices (monitor and audio). The environmental conditions show variation in social and organizational (role, status, and audience) and physical (sound, lighting, etc.).

Generalization in Quantitative Research

According to the *Cambridge Advanced Learner's Dictionary* (2011), a generalization is “a written or spoken comment in which you say or write something very basic, based on limited facts, that is partly or sometimes true, but not always, or when someone generalizes by using such statements.” Consequently, *generalization* is a contentious word. However, there is a consensus that quantitative researchers tend to generalize inferences and findings from a model statistical sample from which the data were collected. Such generalization is known as *statistical generalization*. For getting model statistical samples, chiefly random sampling techniques are used, such as systematic random sampling, stratified random sampling, cluster random sampling, and simple random sampling. However, this uncontrolled use of non-random samples has resulted in null hypothesis significance tests, and consequently, most of the data in behavioral and social sciences remain undistributed. Quantitative research also uses relatively small sample size, and the finding of the small population is generalized to the large population. This calls into question the extent to which interpretations, results, and findings can be justifiably generalized.

Generalization in Qualitative Research

The concept of generalization is also not free from controversy. Researchers believe that approximate generalizations can be made, such as naturalistic generalization, generalizations as representing replication logic, and so on, through qualitative research. They believe that the goal of qualitative research is to gain understanding of particular social, individual, familial, and educational practices and processes that occur within a specific context and location.

In qualitative research, the generalizations are chiefly of two types: case-to-case transfer and analytic generalizations. *Case-to-case generalizations* can be emulated from one type of task to a similar type of task, from one class of users to similar class of users, and from one set of experimental conditions to a similar set of conditions. *Analytic generalizations* address theory more broadly on the basis of how selected cases or layers fit with

general constructs. These are also known as *internal generalization*. Some critics, however, have claimed that qualitative researchers may be prone to error in using a small sample as a basis to generalize their findings in thematic representations. On those grounds, analytic generalization may be criticized as unscientific and therefore contested: How can a single case become the basis of generalization? Robert K. Yin, a specialist in case study design and qualitative research, explains that analytic generalization (internal generalization) happens in two steps: First, the generalization or finding bears upon a specific theory, and second, this theory may be applied in identifying situations in which similar things might happen. For example, the linguist Noam Chomsky's innateness hypothesis holds that at least some knowledge about language exists in humans at birth, and on that basis, Michael Tomasello, a scholar of language acquisition, claims that children have specific cognitive capacities at birth that promote linguistic competence. Further, the psychologist Steven Pinker argues that humans have an innate language instinct. Yin argues that internal generalization does not represent a sample; instead, the goal is to expand and generalize theories.

GENETIC DRIFT

Genetic drift is a process whereby a trait (such as a gene, a protein's specific amino acid sequence, or a phenotypic feature) becomes more or less common in a population. Other ways by which trait frequencies change are mutation, migration, and natural selection. A question that biologists commonly try to settle is whether a certain trait is prevalent in some population because there has been selection for it (because it enhances the likelihood of survival and reproduction) or because there has been selection of it but not for it (because it does nothing to enhance the likelihood or survival and reproduction, but it is linked to traits that have been selected for) or instead because of genetic drift. The importance of drift in the history of life and its precise difference from selection remain objects of research.

Varieties of Drift

One kind of change in trait frequencies that is commonly classified as drift is “indiscriminate parent sampling.” Suppose there is a population consisting of red squirrels and brown squirrels, for which color is a heritable trait. A sudden natural disaster (such as a fire, epidemic, or volcanic eruption) occurs, killing a large fraction of the squirrels. As it happens, a larger fraction of the red squirrels die than do the brown squirrels—not because of any fire-resistance associated with the brown color, but by chance. For instance, perhaps a larger fraction of the red squirrels happened to be in the path of the fire. Consequently, a greater fraction of the brown squirrels than the red squirrels become parents of the next generation. The resulting change in the frequencies of redness and brownness in the population is a result of drift, not natural selection.

In this example, the change in trait frequencies was random in that no difference in fitness between the red and brown squirrels was responsible for it. (For this reason, genetic drift is sometimes called “random drift.”) But although random in this respect, the change in trait frequencies is not inexplicable or the result of irreducible, fundamental randomness in nature (as in the decay of a radioactive atom). For each red squirrel who died, there were causes of its death, and those causes may even have made its survival impossible.

Another kind of change in trait frequency that is commonly classified as drift is the *founder effect*. Suppose that a lake is populated by a given species of fish. Most of these fish have spiky fins, but some have smooth fins instead. Suddenly, a landslide occurs, permanently cutting off one small part of the lake. The fish who were in that part when it was isolated will be the founders of a new population. These founding fish may not constitute a representative sample of the original population. For instance, perhaps by chance all of them have spiky fins—or perhaps the majority have smooth fins. This change in trait frequency is the product of drift, not selection.

This example illustrates that drift can occur even if the various alternative traits that are changing in frequency have different levels of fitness. Perhaps having smooth fins is more effective for swimming than having spiky fins, so having smooth fins instead of spiky fins enhances a fish's fitness. This selective advantage, however, played no role in the frequency change. If having smooth fins was more common in the newly isolated population than it was in the original population, this frequency change was not the result of smooth fins enhancing fitness.

Although drift can occur among traits that differ in fitness, there are thought to be many instances of drift where the traits changing in frequency are equally fit. The individuals in a given population may all have a given protein molecule, but there may be differences among them in the specific amino acid sequence of that protein. These differences may not affect the protein's capacity to perform its biological function, the individual's vulnerability to disease, and so on. In that case, these differences are invisible to selection. Any change in the frequencies of these amino acid sequences (absent mutation and migration) results from drift.

The fish example can also illustrate that drift tends to have a greater impact on trait frequencies insofar as the population is smaller. To the extent that the founding population is a smaller sample taken from the original population, it is to that extent less likely to be a representative sample. The frequencies of spiky fins and smooth fins in the founding population are less likely to match their frequencies in the original population.

An analogy to drift is the random sampling of marbles from an urn. Suppose 30 of the 100 marbles in some urn are yellow and 70 are blue. Suppose I reach into the urn without looking and remove 20 marbles at random. (These marbles are analogous to the founding population of fish.) The proportion of the removed marbles that are yellow may fail to approximate the 30% of yellow marbles in the original population. But if I had removed only five marbles instead of 20, the probability would have been much higher that my sample would have failed to be representative of the original population.

On the other hand, suppose (unrealistically) that the urn contained infinitely many marbles and that an infinitely large sample was drawn randomly from the urn (leaving infinitely many marbles behind). Then, the likelihood of the sample matching the frequencies of yellow and blue marbles in the urn will be arbitrarily high. For this reason, drift is vanishingly weak when the population size is infinite. Of course, no real urn or living population is infinitely large. But biologists sometimes use infinite models to simulate the development of populations. In these models, drift is ignored.

Another kind of case that is commonly classified as drift occurs when a population of sexually reproducing organisms produces a new generation. Some of the parents will contain a gene for one trait and a gene for an alternative to that trait, as when a human being with brown eyes has one gene for brown eyes and one gene for blue eyes. Each gamete will contain only one of these genes. It could happen that among these heterozygote parents, the fraction of their gametes containing the brown-eye gene turns out by chance to be greater than the fraction containing the blue-eye gene. Likewise, even if the two genes are equally represented in the gametes, it could happen by chance that a larger fraction of the brown-eye gametes than of the blue-eye gametes contribute to the next generation. The resulting change in the

population's trait (and gene) frequencies would then be the product of drift, not selection.

The Distinction Between Drift and Selection

In the preceding examples, drift clearly occurs and selection clearly does not. However, there may be many realistic cases where the same trait is subject to both drift and selection or where it is unclear how the case should be characterized.

Suppose that in a population of moths, some are dark and the others are light. Suppose that 60% of the trees have dark-colored bark and 40% have light-colored bark. Dark moths blend in when they land on dark-colored trees but are easier for predators to spot when they land on light-colored trees, and the reverse holds for light moths. Suppose that this difference in camouflage is the only factor at work in selecting for moth color. Since there are more dark than light trees, the dark color in moths is fitter than the light color. However, suppose that during some period of time, the frequency of light moths increases. Although the light moths during that period landed proportionately on light and dark trees, the dark moths happened by chance to land disproportionately on the light trees and so tended to be eaten more readily by predators. Is this change in the moth population's trait frequency a result of selection or drift?

Drift appears to be operating because it was just by chance that during this period, dark moths landed disproportionately on light trees. But selection also appears to be operating, since on a light tree, dark moths are at a selective disadvantage. Moth color makes a difference to the likelihood of predation and predation was responsible for the change in color frequency. The sampling of moths was not indiscriminate; moth color, which is responsible for moth fitness, made a difference.

Although the dark moths were fitter than the light moths, the light moths increased in frequency. This does not mean that natural selection was not operating. Selection is a statistical process. A fitter trait is more likely than a less fit trait to increase in frequency, but it is not certain to increase in frequency. Unlikely outcomes (like a long run of heads from a fair coin) sometimes happen. That the outcome was unlikely does not mean that the likelihoods (in our case, the fitnesses) were not responsible for the outcome. An improbable result of selection is no less a result of selection than a

more probable result of selection (though it may be more difficult to ascertain the traits' relative fitnesses if their fitnesses make the result unlikely).

What, then, distinguishes a result explained by selection from a result explained by drift—or are some outcomes explained by both? One suggestion is that selection explains a change that the traits' fitnesses make likely whereas drift explains a change that the traits' fitnesses make unlikely. This view would construe the decline in the frequency of dark moths as drift, not selection, even though predation and moth color (which are responsible for the traits' fitnesses) produce this result. Conversely, a frequency change can have been likely, considering the trait fitnesses, and nevertheless can have been the product of drift rather than selection. For instance, suppose that a goldenrod population consists of equal numbers of plants producing smooth seeds and plants producing wrinkled seeds. Suppose that the trait of producing smooth seeds is fitter. However, a rare flood occurs, killing nearly all of the population's members. The only survivors are the few plants that were living outside of the flood zone, and by chance, more of them produce smooth seeds than wrinkled seeds. This increase in the frequency of the smooth-seed trait is just what was likely, considering the trait fitnesses. Yet this is a case of drift, not selection.

Another suggestion is that whether an outcome is explained by selection or drift is not determined by whether the outcome is caused by the factors responsible for the traits' fitnesses. Rather, an outcome is explained by drift exactly when it is a characteristic manifestation of the fact that selection is a statistical (i.e., a chancy) process. That the light moths increase in frequency, even though the dark moths are fitter, is a product of drift in that this outcome is made possible by the fact that selection is a statistical process. Population biology likewise treats the occurrences of rare population bottlenecks (such as the flood that nearly wiped out the goldenrod population or the small founding population of fish) as statistically freak events—flukes that are bound to happen from time to time in the long run but are unlikely in any short run. Similarly, that two populations starting with the same trait frequencies and experiencing the same selection pressures (and no mutations and migrations) diverge in their trait frequencies is explained by drift not because the trait fitnesses are irrelevant to the final trait frequencies but because this divergence is characteristic of

statistical processes. It is not as if one of these two populations experienced only selection and the other experienced only drift. The difference between them is explained by drift even though selection was operating on both populations.

GEOLOGY

Geology, Greek for *Earth study*, is exactly how it reads: the science of the Earth. This can be defined as the solid or liquid components that comprise Earth our planet, but also the science of solid and liquid structures on other celestial bodies such as the Moon or Mars. Geology uses scientific methods to explore and understand the dynamics of the planets, their resources, and their sustainability through time. One major component of geology is the introduction of deep time by 18th- and

19th-century theorists, on the basis of physical evidence as opposed to biblical chronology. Thus, geology includes the study of events that happened thousands, millions, and even billions of years ago and processes that spanned thousands, millions, and sometimes billions of years.

Geology is a complex and variable field. Geoscientists often specialize in one discipline within geology that often overlaps strongly with another scientific field (e.g., chemistry, biology, physics). A few of the major disciplines in geology are described here. *Geochemistry* is the investigation of chemical elements in rocks and minerals to help explain mechanisms behind formation, distribution, and deformation. *Geochronology* is the science of timing, duration, and rates of Earth processes and events. *Geomorphology* is the study of present-day landforms and their processes of formation. *Geophysics* is the branch of science that studies the interior properties of the Earth, often using remote sensing techniques. *Hydrogeology* is the study of the movement of water beneath the Earth's surface. *Paleontology* is the study of life on Earth. *Petrology* is the description of rocks and rock-forming minerals including processes that form and later alter them. *Resource exploration* is the discovery and exploitation of important resources (e.g., water, hydrocarbons, minerals). *Structural geology* is the study of rock deformation and map making. There are branches of science that are closely related to geology including atmospheric science, anthropology, climatology, environmental science, geotechnical engineering, and oceanography; these are all very important Earth-related sciences but are outside the scope of this entry.

The importance of geology cannot be overstated. Almost everything a person uses daily is at least partly a result of work by a geologist. Some examples of everyday rewards of geology include the gasoline used to run a vehicle, the diamonds for an engagement ring, plastic containers for storage, and metals used in construction. Furthermore, geology can be linked to certain famous works of art, and geological factors have sometimes led to wars between nations.

Structure of the Earth

When the Earth was first formed, it likely had a uniform composition from core to crust. Through time the Earth was subject to compression caused

by gravitational forces and radioactive decay of elements; these processes increased the temperature and pressure within the planet, resulting in a series of layers forming that differed by density and composition. On Earth and other planets, temperature increases with depth. For example, at or near the Earth's surface rocks are close to 0°C; temperatures increase to approximately 7,000°C at the Earth's core. The rate of temperature increase, called the *geothermal gradient*, increases approximately 30°C for every kilometer of depth. The continuous flowing of heat outward from the interior of the Earth induces convection beneath the crust; this convection is the driving force behind the movement of tectonic plates (discussed in the Plate Tectonics section of this entry).

Geoscientists describe the concentric layers that comprise the Earth by either rheology or composition. *Rheology* is the study of physical properties at different depths and pressures, and composition is the chemical makeup of Earth's layers. Both are described in detail below.

Composition of the Earth

If defined by composition, the Earth has three layers from listed from outside to inside: crust, mantle, and core. The *crust* is dominantly composed of light silicate minerals and is further separated into continental crust and oceanic crust. Continental crust underlies most landmasses and is dominantly composed of the rock *granite*, which has lower density and is thick (approximately 35 km) when compared to oceanic crust. Oceanic crust makes up most of the rock found at the bottom of the ocean floor and is dominantly composed of the rock *basalt*, which has higher density and is thin (approximately 8 km thick).

Underlying the crust is the mantle. The *mantle* is composed of high-density iron- and magnesium-silicate rocks. The mantle extends to a depth of 2,885 km. Beneath the mantle is the iron-, nickel-, and sulfur-rich core. The core extends to the center of the Earth, which is 6,371 km deep.

Rheology of the Earth

According to rheology, the Earth can be separated into five layers listed from outside to inside: lithosphere, asthenosphere, mesosphere, outer core, and inner core. The *lithosphere* is cool, solid,

and brittle. It extends from the surface to an average depth of 100 km. If correlated to the compositional layers of the Earth, the lithosphere comprises all the crust and the upper part of the mantle.

Beneath the solid lithosphere is the *asthenosphere*. The asthenosphere behaves in a plastic manner, which means that it is capable of flow when gradual forces act upon it. The asthenosphere extends from the lithosphere at 100 km depth to approximately 700 km depth. If correlated to the compositional layers of the Earth, the base of the asthenosphere matches with the base of the upper mantle.

Beneath the plastic asthenosphere is the plastic, but more rigid, *mesosphere*. The mesosphere behaves differently from the asthenosphere in that it is subject to more extreme temperatures and pressures with increased depth. The mesosphere extends from the base of the asthenosphere (ca. 700 km) to a depth of approximately 2,885 km. If correlated to the compositional layers of the Earth, the base of the mesosphere matches with the base of the mantle.

The *outer core* is liquid and capable of flow. The outer core extends to a depth of approximately 5,155 km. Beneath the outer core is the solid *inner core*. The inner core is rigid and the most dense of all layers within the Earth. The inner core extends all the way to the center of the Earth (6,371 km deep).

How Do We Know Earth's Internal Structure?

The internal structure of the Earth has not been directly sampled. The layers within are interpreted mostly by remote-sensing techniques. Some techniques that inform us about the interior of the Earth include *seismic waves*, sound waves that propagate through the Earth after an earthquake. Many earthquakes analyzed through time have produced detailed, three-dimensional images of the Earth. Seismic waves change their speed and direction depending on the physical properties of the material through which they pass, which is how geoscientists identify the different rheological and compositional boundaries.

There are two main types of seismic waves, P waves and S waves. *P waves*, or longitudinal waves, travel in the direction of propagation and can transmit through all material properties (liquids and

solids). *S waves*, or transverse waves, travel perpendicular to the direction of propagation and are only able to travel through solids. Comparing P waves to S waves, geologists are able to determine the rheological properties of the Earth. For example, because the outer core is liquid, S waves dissipate at the contact between the mesosphere and the outer core.

Age of the Earth

The Earth is approximately 4.6 billion years old. This age has been calculated by dating rocks and minerals found on the Earth's surface. The oldest terrestrial mineral on Earth is a zircon from Western Australia; zircon contains the element uranium, which enables scientists to use the process of uranium-lead radiometric age dating (discussed below) to determine accurate ages for mineral formation. The zircon from Western Australia has been dated as 4.4 billion years old. This mineral has survived for so long because it is nearly indestructible; zircon can be weathered, eroded, and redeposited many times.

Because the Earth is so old, it may be difficult to comprehend the time it takes for geologic events to occur. For example, sediment from a river may accumulate over centuries to create a singular sandstone bed. Geologists have developed ways to segment Earth's history into temporal groupings based on the age of rocks, minerals, and the appearance/disappearance of fossils.

Geologic Time Scale

One of the most valuable contributions geologists have made to the scientific community is the Geologic Time Scale. The passage of time on Earth is divided into geochronological units that can be referred to as years before *present* or by given names. *Years before present* means since 1950; however, because geological time is usually measured in millions of years, this is an unnecessary distinction. For example, the Cambrian Period spanned from 541 to 485 million years ago (Ma).

The divisions in the Geologic Time Scale vary in range and include *eons*, *eras*, *periods*, *epochs*, and *stages*. Time on Earth can be separated into four eons: the Hadean from 4.6 to 4.0 billion years ago (Ga), the Archean from 4.0 to 2.5 Ga, the Proterozoic from 2.5 Ga to 541 Ma, and the Phanerozoic from 541 Ma to present. These eons

represent major changes on Earth for which geoscientists made special note. For example, the start of the Phanerozoic Eon corresponds to the beginning of recognizable life on Earth. *Eras* are large separations of time and include the common separations of time in the Paleozoic (541 to 251 Ma), Mesozoic (251 to 66 Ma), and Cenozoic (66 Ma to present). Periods, epochs, and stages of time are used mostly when examining detailed sections of rock. For example, many people recognize the Cretaceous Period as the time when dinosaurs such as *Tyrannosaurus rex* roamed the Earth.

Absolute Dating

Most rocks on Earth contain, even in trace amounts, radioactive materials. The three radioactive elements on Earth are uranium, thorium, and potassium. Radioactive elements spontaneously decay, or break apart, over the course of time into atoms of other elements. Decay commences as soon as a rock is produced and the time this decay takes is consistent, so it can be measured in a lab. A half-life is the time it takes for half of the atoms of one element to decay to other atoms. For example, uranium 235 decays to lead 207; the half-life of this decay is 704 million years. By comparing the number of each atom type in a rock, geologists can determine how long the rock has been decaying. Because decay begins immediately after a rock is formed, when decay is measured the absolute age of a rock can be determined. The process of discovering absolute ages is called *radiometric age dating* and is a powerful tool in understanding the age of the Earth and the events that occurred upon and within it.

Relative Dating

Relative dating is the practice by which rocks can be correlated and compared across vast geographic areas to determine an order of events without necessarily knowing absolute ages. This can be done at outcrop scale by following basic principles of *stratigraphy*, which is the study of layered rocks to determine the order and timing of events in Earth's history. The main principles of stratigraphy are superposition, original horizontality, lateral continuity, cross-cutting relationships, inclusions, and faunal succession. The

principle of *superposition* states that in an undeformed sequence of layered rocks, the layers at the bottom are oldest and the rocks at the top are youngest. The principle of *original horizontality* states that layers of rock are deposited horizontally with some rare exceptions (e.g., igneous dykes, slope margins). The principle of *lateral continuity* states that strata are widely distributed in all directions until they reach some barrier or travel too far from the source. The principle of *cross-cutting relationships* states that any rock or mineral that cuts across another is always younger than the host rock. The principle of *inclusions* states that fragments of another rock housed within a separate rock are always older than the host rock. Finally, the principle of *faunal succession* states that organisms undergo successive changes through time, and rocks that contain fossils can therefore be compared and characterized as younger or older. The most effective fossils are those that have a large spatial distribution but a narrow temporal range. By using these stratigraphic principles, the relative timing of events in a series of rocks can be interpreted.

Plate Tectonics

Another invaluable contribution to the science of the Earth is the theory of plate tectonics, which holds that the rigid plates made up of the rigid lithosphere move on top of the plastic asthenosphere. This theory is used to explain features on Earth such as oceans, mountain ranges, volcanoes, and earthquakes. Plate tectonic theory stemmed from observations that continents separated by oceans (e.g., South America and Africa) have complementary shapes, remains of unique animals and plants (e.g., *Cynognathus* an extinct mammal ancestor from the Triassic period) being found on all southern hemisphere landmasses, and similar sequences of rocks being described across oceans. These observations culminated in a theory that tectonic plates come together and move apart through time, thereby creating mountains, ocean basins, deep sea trenches, and hotspot volcanoes. This process of continents moving apart and coming together is called a *Wilson cycle*—named after the Canadian geophysicist J. Tuzo Wilson (1908–1993)—and takes approximately 200 million years. There are currently seven major tectonic

plates on Earth: African, Antarctic, Eurasian, Indo-Australian, North American, Pacific, and South American. These major plates are in constant motion at rates varying from a few millimeters to a few centimeters per year.

As discussed previously, the lithosphere beneath oceans is called the *oceanic crust*. Oceanic crust is dominantly composed of mafic igneous rock (e.g., basalt, gabbro) that is sourced from molten material that erupts at places where two tectonic plates move apart from each other. Oceanic crust has a density of approximately 3.0 g/cm^3 and is relatively thin compared to continental crust (approximately 8 km). Continental crust underlies the continents and is composed of dominantly less dense (2.7 g/cm^3) light-colored igneous rock (e.g., granite) that ranges in thickness from approximately 25 km to 70 km in mountainous regions. Boundaries between continental crust and oceanic crust are called *continental margins* and often extend underwater hundreds of meters to hundreds of kilometers off the coastline.

There are three main types of contacts between tectonic plates: transform, divergent, and convergent. *Transform boundaries* are found when parts of the plates move along each other without any crust being created or destroyed. Arguably, the most famous transform boundary is the San Andreas Fault in the southwestern United States. The fault associated with this boundary has moved many times during the recent geological past and is constantly monitored by the United States Geological Survey. *Divergent plate margins* are places where tectonic plates move apart from each other and new crust is created. Examples of divergent plate boundaries where two tectonic plates are currently moving apart are the mid-Atlantic ridge and the east African rift valley. *Convergent margins* are places where tectonic plates move toward each other and where crust is destroyed. These convergent margins can occur where oceanic crust meets oceanic crust, where oceanic crust meets continental crust, or where continental crust meets continental crust. These interactions result in one plate; the less dense plate overrides the more dense plate and the more dense plate goes down into the asthenosphere in a process called *subduction*. As the denser plate is forced down beneath the less dense plate, pressure and heat increase. This can melt the overlying rocks, which may then

erupt as a series of volcanoes within the overriding plate, parallel to the tectonic boundary. An example of a subduction zone where two oceanic plates approach each other and volcanoes form is that of Japan. An example of a subduction zone where an oceanic plate subducts beneath a continental plate is that of the western coast of North and South America. Finally, where two continents converge, there is often a thickening of the crust with or without associated subduction. An example of a *continent–continent collision* is that of the Himalayan mountains. The friction produced by this plate collision can cause large earthquakes that may be experienced through tsunamis thousands of kilometers away from the focus of the earthquake itself.

Rocks and Minerals

A large component of geology is the study of rocks and minerals. The Earth is made up of naturally occurring elements (e.g., hydrogen, oxygen, carbon, silicon, magnesium, iron) that combine to make minerals. A *mineral* is defined as a naturally forming, inorganic, crystalline substance with a specific chemical composition. Common minerals include quartz, feldspar, amphibole, and mica.

A *rock*, in comparison, is a combination of multiple (two or more) minerals. There are three main rock types: igneous, metamorphic, and sedimentary. The three rock types vary in how they form or are deposited. All rock types can, and do, form from the remnants of older rocks in an endless loop called the *rock cycle*.

Igneous Rocks

Igneous rocks form from molten material that has cooled and crystallized. Molten material may be lava, material that has erupted at the Earth's surface, or magma, material that has crystallized in the subsurface at depths up to a few kilometers. Rocks formed from lava are called *extrusive* igneous rocks. Extrusive rocks cool over a period of seconds to days and so have very small to invisible mineral crystals. Rocks formed in shallow magma bodies are called *intrusive* igneous rocks and rocks formed in deep magma bodies are called *plutonic* igneous rocks. Intrusive igneous rocks cool over hundreds to thousands of years and have small- to medium-sized

mineral crystals. Plutonic rocks cool over millions of years and often have very large crystals.

Molten material is classified according to the amount of silica present, which is reflected in the dominant minerals crystallized. *Felsic* magma contains 65% to 75% silica by weight; common minerals in felsic igneous rocks are light minerals like quartz and feldspar. Examples of felsic igneous rocks are granite and rhyolite. *Intermediate* magma contains 52% to 65% silica by weight; intermediate igneous rocks have a near-equal mix of light (e.g., quartz, feldspar) and dark minerals (e.g., amphibole, biotite). Examples of intermediate igneous rocks are andesite and diorite. *Mafic magma* contains 45% to 52% silica by weight; mafic igneous rocks are dark in color and commonly contain minerals like pyroxene and plagioclase feldspar. Examples of mafic igneous rocks are basalt and gabbro. *Ultramafic magma* contains less than 45% silica; ultramafic rocks are dark in color and are quite rare. Examples of ultramafic rocks include komatiite and peridotite.

Igneous rocks are formed in three different places: divergent plate boundaries, convergent plate boundaries, and hot spots. The magma produced at divergent margins often is mafic in composition. Convergent plate boundaries are places where two tectonic plates move toward each other. The magma composition at these boundaries often has higher silica content (i.e., produce felsic igneous rocks). Subduction zones are one type of convergent plate margins. A subduction zone occurs when one tectonic plate approaches another tectonic plate, and the denser plate moves underneath the less dense plate. As the denser plate descends, magma can rise to the surface and form volcanoes. Hot spots are places where molten material rises to the surface not at a plate boundary and cool very quickly. A famous example of a hot spot chain is that of the Hawaiian islands.

Sedimentary Rocks

Sedimentary rocks are very common at the Earth's surface as they are composed entirely of other rocks that have been broken down, transported, and redeposited. Sedimentary rocks are described on the basis of their physical properties including composition, color, texture, fabric, and porosity. A large part of describing sedimentary

rocks is the discussion of depositional environments. Sedimentary rocks can be formed in terrestrial environments including rivers, deltas, lakes, and deserts or in marine environments such as reefs, continental slopes, and abyssal plains. There are two broad groups of sedimentary rocks: siliciclastic and biochemical. *Siliciclastic* rocks are the residues of weathering and erosion (e.g., conglomerate, sandstone, mudrock); *biochemical* rocks are accretions of biological, biochemical, or chemical material (e.g., fossiliferous limestone, coal, evaporites).

Siliciclastic sedimentary rocks form as a result of weathering, erosion, deposition, and lithification of sediment. Weathering is the breakdown—physical, biological, or chemical—of older rock to produce smaller minerals and rock fragments. These weathered fragments are transported from one place to another in a process called *erosion*. Erosion of sediment occurs by the action of water, wind, ice, and/or gravity. Eventually sediment is laid down or deposited. If left for long periods of time, the sediment then undergoes diagenesis. Diagenesis begins with burial and lithification; *lithification* is the process of turning loose sediment into rock. Compaction and cementation, or the pressing down of overlying sediment on top of buried sediment and the gluing together of the sediment by accreting small minerals between grains, are the dominant diagenetic processes occurring soon after deposition.

Biochemical sedimentary rocks are formed by the inorganic or organic chemical precipitation of particles after chemical weathering. Unlike siliciclastic sedimentary rocks, biochemical sedimentary rocks are precipitated directly in a depositional environment without transportation. These rocks are classified chiefly on the basis of their mineral composition. For example, rock that forms by precipitation of calcite is called *limestone*, rock formed from dolomite is called *dolostone*, halite and gypsum are called *evaporites*, and inorganic silica is called *chert*. These sedimentary rocks often include *allochems*. Allochems are grains that are not formed by precipitation from seawater but are extra material, often fossils (e.g., shells, feces, cyanobacteria).

Metamorphic Rocks

Metamorphic rocks, the third main rock type, always have had a previous history as a parent

igneous, sedimentary, or even an older metamorphic rock. These parent rocks undergo a significant change resulting from high temperature and/or pressure. The change from a parent rock to a new metamorphic rock happens in one of three ways: contact with heat (i.e., contact metamorphism), burial (i.e., burial metamorphism), or plate collision (i.e., dynamothermal metamorphism). *Contact metamorphism* occurs when molten material passes near, or through, older host rocks. These host rocks are heated and transformed, recrystallizing or even producing new minerals. *Burial metamorphism* occurs when rocks are deeply buried and thus exposed to the higher temperatures and pressures that exist in the lithosphere. *Dynamothermal metamorphism* occurs when two tectonic plates converge, which produces high-pressure environments such as mountain belts.

The amount of temperature and/or pressure to which a parent rock is exposed produces new minerals, called *index minerals*, in a predictable order. Index minerals in metamorphic rocks from low grade to high grade are chlorite, muscovite, biotite, garnet, staurolite, kyanite, and sillimanite. Low-grade metamorphism, whereby rocks are exposed to relatively low temperature and pressure, occurs when the metamorphosed rock retains characteristics of the parent rock. High-grade metamorphism, whereby rocks are exposed to relatively high temperature and pressure, occurs where the newly produced rock no longer resembles the parent rock. When pressure is the more dominant process (compared with temperature), compositional bands, called *foliations*, can form as minerals reorganize (e.g., gneiss).

Common metamorphic rocks formed from layered parent rocks in order from low to high grade are slate, phyllite, schist, gneiss, and migmatite. Metamorphic rocks formed from unlayered or massive parent rocks include marble, quartzite, and hornfels.

Geological Structures

To understand the geological history of an area, geoscientists need to confidently identify rocks and minerals, but they also must be able to interpret geological structures. Structures are variations, spatial or directional, in the properties of

the Earth's crust. These structures tell us how the Earth has changed through time. For example, where one type of rock contacts another there is a geological boundary, a type of structure. Geological boundaries include bedding planes, faults, intrusive contacts, and unconformities. These different boundaries inform geoscientists about the history of an area.

Some geological structures are formed at the same time as the rocks in which they are found. These structures are called *primary structures* and include features like laminae and bedding in sedimentary rocks, or lava pillows and flow banding in igneous rocks. However, many structures are formed long after the rocks in which they are found. These structures are called *secondary structures* and include foliation in metamorphic rocks, folds, unconformities, and fractures. Secondary structures are products of deformation, which is the movement of parts of the crust relative to one another.

The Earth's crust contains primary and secondary structures nearly everywhere; a major aspect of geology is that of documenting and understanding these structures. There are three levels in the understanding of geological structures: *descriptive analysis* (i.e., the positions, orientations, sizes, shapes of structures), *kinematic analysis* (i.e., how the rock has been deformed or strained), and *dynamic analysis* (i.e., the forces, or stresses, that operated to deform the rocks to their present orientation).

A powerful representation of geological structures is a geological map. Geological maps are created by visiting rock outcrops during fieldwork and interpreting the areas between the outcrops. Geological maps are produced at a variety of scales that have variable levels of detail. For example, a 1:50,000 map (i.e., 1 cm on the map equals 500 m in the real world) is a common map scale used for regional geology, whereas a 1:1,000 map (i.e., 1 cm on the map equals 10 m in the real world) is a useful scale for resource exploration.

Life on Earth

The Earth became habitable for life approximately 4.4 billion years ago. Gases released by volcanic eruptions and extraterrestrial impacts formed a thick atmosphere around the Earth, consisting of

carbon dioxide (CO₂) and small amounts of nitrogen, water vapor, and sulfur. Once the Earth had cooled enough to have a solid crust, liquid water accumulated in basins, forming the oceans that cover much of the planet today. Evidence of life on Earth has been preserved as fossils in rocks; *paleontology* is the study of fossils as once-living organisms.

A fossil is a remnant of an organism preserved in the rock record. These remnants include parts of the original organism (body fossils), imprints or other indirect evidence of life (trace fossils), or molecular compounds produced by organisms (chemical fossils). All fossil types provide information about the organisms that made them and about the environment in which the organism lived or died.

The oldest evidence of life on Earth are stromatolites in rocks 3.5 billion years old. *Stromatolites* are domes of finely laminated sediment and microbial mats that still exist today in places such as Shark Bay, Australia. Complex lifeforms that can be identified as ancestors to groups of living organisms today arose in the Ediacaran to Cambrian Periods, approximately 635 to 530 Ma. Some examples include shelly fossils, corals, arthropods, sponges, and worms. The success of life at this time on Earth can be attributed to the following mechanisms: predation increasing ecological diversity, increase in Earth's oxygen concentration, and the increase in organic matter in oceans. From the Ediacaran onward, evidence of life on Earth increased dramatically. Most sedimentary rocks contain organic matter. Geologists use this information to reconstruct what the Earth was like through its long history.

GEOMETRY, CLASSICAL

Geometry has a special role in mathematics because of its connection with physical space. Today this might not be the only force, or the driving force, behind the development of new geometries, but in the ancient world it was an important aspect. Geometry was considered an access point to deeper insights about how the world is constructed and how it connected to our reasoning.

Geometry can be thought about in many different ways. We know this from today's geometries, which can be quite challenging for our experiences, which are derived from a normal three-dimensional perception of the universe. There were also different ways to develop geometry in, for example, ancient Greece, but one of them came to play a dominant role—namely Euclidean geometry. This geometry has played a paradigmatic role in mathematical thinking, and this entry traces its development and its sources as well as its impact on modern conceptions of nature.

The first section discusses pre-Euclidean geometry and the manifold roots of geometry. Next we present the Pythagorean ideas on geometry, and in particular the idea that the world consists of numbers (or of number units). This is followed by a discussion of Plato's idea that geometric concepts belong to an eternal world of ideas. The entry continues with a presentation of Euclid's *Elements*, with reference to his definitions, axioms, and theorems. We then explain how Euclid's conception of geometry differs from Archimedes' conception, and how Euclid's conception turned into an epistemic paradigm, stating that knowledge has to be organized in an axiomatic framework. This epistemic paradigm dominated for centuries, and also influenced how Nicolaus Copernicus, Johannes Kepler, Galileo Galilei, and Isaac Newton developed their approaches toward a modern science. The entry concludes with a summary of the ontological, epistemological, sociological, and

ethical issues related to the development of classical geometry.

Pre-Euclidean Geometry

In Greek, the word *geo* means “earth” and the word *metron* means “measurement,” so an etymological interpretation of the word *geometry* could be *land measuring*. As already observed in antiquity, such an interpretation related very closely to its utility. In Egypt, whenever the Nile River went over its banks and flooded the farmland, the boundaries between the different plots of land disappeared. They then had to be restored, and this presupposed land measuring. The same processes took place in Mesopotamia whenever the rivers Euphrates and Tigris flooded the farmland. In order to complete these restorations, geometry represented a set of useful knowledge, mastered as part of some everyday life practices.

In antiquity, geometry was also brought into action with respect to impressive constructions, the Egyptian pyramids being among the most remarkable examples. Their very existence demonstrates the presence of a profound geometric knowledge necessary for both the planning and the building of the pyramids. Just to make a single and possibly almost trivial point: The accurate construction of right angles must have been well known.

Ancient cities like Babylon were architectural wonders, and so was the architecture developed in India, China, and Japan. We also need to remember the Mayan civilization in South America, which from around 750 B.C.E. created remarkable cities and, from around 500 B.C.E., unique pyramid-like constructions. For certain, the Parthenon temple on top of the Acropolis in Athens demonstrates a unique mastery of geometry. The building of the Parthenon started around 490 B.C.E., but its construction presupposed competences and techniques developed over centuries and with resources from all over the ancient world. All these architectural achievements reveal profound masteries of geometry.

Geometry not only forms part of unique architectures, but it also constitutes part of everyday life constructions like houses, dams, and ships. Such constructions draw on geometric insight, although this could well be in an implicit format.

It is the existence of this form of geometric insight that we also need to bear in mind when considering the roots of geometric knowledge.

Geometric-based achievements are not restricted to physical constructions but can also form part of theoretical constructions. Astronomic observations have been completed at many places, and different geometric interpretations of what was taking place in the sky have been formulated. Mesopotamia was known for its detailed astronomic observations. Thales (ca. 624–548 B.C.E.), at times referred to as the first Greek philosopher, is known for having predicted a solar eclipse that took place in 585 B.C.E.. This might be true; however, it is not very likely that he was able to do so based on his own observations, but more likely that he drew on astronomic insight developed in Mesopotamia. This insight did rest on a sublime mastery of geometry. Thales came from Miletus, located at the coastline of Turkey with good connections to more Eastern regions with geometrical knowledge.

From these manifestations of pre-Euclidian geometry, it should be recognized that geometry refers to a diversity of forms of knowledge and techniques, rooted in different cultures and contexts. With this diversity in mind, let us now concentrate on a particular route in the theoretical development of geometry.

Pythagorean Thoughts

According to legend, Pythagoras (ca. 570–495 B.C.E.) was born on Samos, a Greek island on where the municipality of Pythagoreio, also called *Pythagorion*, has been named after him. About the person Pythagoras, we know very little. He operated in some closed circles that adopted a range of rituals and ideas, and the Pythagorean community took on what today could be considered a religious character.

One of the ideas advocated by the Pythagoreans was that the world is built up of numbers. This claim might sound strange to us today, but numbers can be thought of as being small units, so one can see the Pythagorean claim as a kind of preliminary version of an atomic theory. In fact, such a theory was later developed by Democritus (around 460–370 B.C.E.), who stated that everything is composed of small units, and he enumerated different types of such atomistic units.

The name of Pythagoras is associated with the Pythagorean Theorem, a theorem that was already known a thousand years earlier in an Indian context. Paradoxically it brings a devastating blow to Pythagorean metaphysics. According to the theorem, the length of the hypotenuse in the right-angled triangle with the legs having the length 1 is the square root of 2. If everything consists of numbers, the length of the sides in this right-angled triangle should be composed of an exact amount of small number units. In other words, the square root of 2 should be a rational number, and these were exactly the numbers known and operated on by the Pythagoreans. However, it can be easily proved that the square root of 2 cannot be a rational number. The Pythagoreans demonstrated this, although in a way different from how we would prove it today.

The proof rocked the Pythagorean community. There does not exist a fraction generated by a number of units (what we would call a rational number) out of which a line the length of the square root of 2 can be composed. Apparently then, the world cannot be composed of numbers as the Pythagoreans knew them.

Extraterrestrial Geometry and Axioms

Plato (ca. 425–348 B.C.E.) gave high esteem to mathematical insight which at the time was mostly geometric. He was fully aware of the Pythagorean insights, and he created a different metaphysics with respect to mathematical entities.

To Plato the world we experience is not composed of numbers; in fact, he argued, we cannot find any mathematical entities in this world. Such entities all belong to a world of ideas. We cannot access this world by means of our senses, only by our rationality. In our experiential world, we find many triangles, but they are not *real* triangles as we understand through formal definitions. The properties of physical triangles are only approximations of the properties of real triangles. The sum of the angles we might measure in a physical triangle may be more or less the same as the sum of two right angles, but rarely exactly so. The Pythagorean Theorem might apply more or less approximately to physical triangles with a right angle; however, the theorem only applies precisely to the real right-angled triangles, and such

triangles all belong to the world of ideas. That the Pythagorean Theorem does apply to such triangles can be proved through pure reasoning, without us doing any measuring at all in the physical world.

Aristotle (385–322 B.C.E.) presented a general format for how any body of knowledge should be presented, be it with respect to biology, ethics, or anything else. As we will see in a moment, Euclid's geometry became the quintessential example of this axiomatic approach. Aristotle argued that a science needs to start with definitions of the necessary concepts. These would be followed by a list of axioms, and from these axioms the body of the theory should be developed through logical deductions. Aristotle had developed what at the time was considered the only imaginable logic, and he knew exactly how many valid argument structures existed. In this way, Aristotle outlined the general structure of knowledge as represented in an axiomatic format.

Euclid's *Elements*

In the *Elements*, Euclid (ca. 325–265 B.C.E.) presented an axiomatization of geometry. Aristotle formulated his knowledge paradigm well before Euclid brought together the *Elements*; but long before Euclid did so, there had been many attempts to produce a set of axiomatizations in geometry. The one presented by Euclid did draw on these previous efforts and became the most coherent.

The *Elements* starts out with some definitions; thus, a point becomes defined as that which cannot be divided. Then follow five axioms, which should be understood as the construction techniques allowed within the axiomatic system:

1. To draw a straight line from any point to any point.
2. To produce (extend) a finite straight line continuously in a straight line.
3. To describe a circle with any center and radius.
4. That all right angles equal one another.
5. That, if a straight line falling on two straight lines makes the interior angles on the same side less than two right angles, the two straight lines, if produced indefinitely, meet on that side on which the angles are less than the two right angles.

The fifth axiom can be given different formulations; one such is:

6. Through a given point P outside a given line L, there can be drawn one and only one line parallel to L.

With these axioms as the starting point, the deduction starts, and theorem after theorem is proved in the 13 volumes that constitute Euclid's *Elements*. Geometric constructions are well-defined procedures whereby only two instruments are allowed: the compass and the ruler. Constructions should be made by circles and straight lines, and only by these two simple geometric figures. The first theorem in the *Elements* states that an equilateral triangle can be constructed.

The proof that a certain geometric figure can be constructed is similar to showing that this figure does exist in the world of ideas, at least according to Plato's interpretation. It also turned out that certain constructions are difficult, like the trisection of an angle. Later it was proved that it was in fact impossible to make this trisection by means of compass and ruler.

Euclid concludes the *Elements* by showing that it is possible to construct the so-called Platonic solids: the tetrahedron, cube, octahedron, dodecahedron, and icosahedron. These *regular* and *convex polyhedrons* had been investigated carefully long before Euclid did so, and it was well known that the five Platonic solids were the only possible regular solids. In finishing his exposition by investigating the Platonic solids and how they can be constructed, Euclid reached a powerful conclusion of a study that was initiated by showing the construction of an equilateral triangle.

We do not know much about the person that was Euclid. He worked in the Egyptian city of Alexandria and he wrote in Greek, the academic language of the time. However, he need not have been born in Greece but could have come from Egypt, from Mesopotamia, or from many other places, as the academic world at that time involved travel and interaction.

Geometric Paradigms

The *Elements* set out a paradigm for geometric thinking that turned into a paradigm for how to organize knowledge in general. This paradigm stayed dominant for more than two thousand

years, although it was not the only conception of geometry that was established.

Archimedes (ca. 287–212 B.C.E.), living much of his time in Alexandria, contributed profoundly to geometry; however, he did not operate within the Euclidian paradigm. Archimedes showed how a trisection of an angle could be constructed. In doing so Archimedes used a spiral, which according to Euclidian measures was not allowed. It was simply not part of the axioms of the Euclidean system, and it shows how values and normative decisions played a significant role in the otherwise clean and logical birth of Euclidean geometry. The straight line and the circular motion were considered the eternal movements in the Platonic approach and were hence chosen to be the foundation of proper constructions in geometry.

By operating with infinitesimals, Archimedes went far beyond the deductive pattern presented in the *Elements*. By doing so, he was for instance able to calculate the exact volume of a surface and of a sphere. Archimedes was preempting the reasoning much later applied in calculus and differential geometry, but such reasoning remains foreign to the Euclidean paradigm and was therefore not handed down from generation to generation in the training of practitioners of geometry.

Throughout antiquity, geometry was brought into action for planning and completing architectural constructions: building temples, aqueducts, bridges, dams. Vitruvius (ca. 85–20 B.C.E.) wrote the book *On Architecture* (*De Architectura*), which appeared in 10 volumes. He highlighted the importance of geometry for completing any architectural construction. In *On Architecture*, we are dealing with a conception of geometry quite different from the one set by the Euclidian paradigm. We are dealing with what later became referred to as *descriptive geometry*. One important challenge to descriptive geometry is to provide two-dimensional descriptions of three-dimensional objects. This branch of geometry has been applied during all subsequent historical periods and became further refined as part of the Industrial Revolution, when many new machines had to be described before actually being constructed. In German, descriptive geometry is called *darstellende Geometrie*, where the word *darstellende* can be interpreted as “performing” or “manufacturing.” This etymological interpretation highlights that through geometry

one *performs* a possible construction—a feature of geometry that was anticipated by Vitruvius.

Geometries of the World

Geometry has been widely used for formulating worldviews about the cosmos and the positioning of sun, earth, and planets. This connection continues the tradition from the Pythagoreans, Plato, and Euclid to connect geometry to the laws governing physical space on an astronomical scale.

An important such geometric worldview was formulated by Ptolemy (around 100–170), who lived in Alexandria. This view acknowledges the Aristotelian outlook by placing the earth at the center of the universe and by considering all heavenly movements to be circles.

Ptolemy had access to a huge number of astronomical observations, meaning that the actual movements of the planets in the sky were well documented. Unfortunately, however, these observations did not fit any simple model of the universe with the movements of the planets presented as circles with the earth at the center. Whatever size that was looked at for the radius of the circles one assumed, a gap occurred between model and observations. Owing to fundamental metaphysical assumptions at the time, one had no alternative but to take as a given that heavenly movements were circles and to attempt to repair the model by introducing a number of epicycles. An *epicycle* is a circle with its center positioned at the periphery of another circle, so by operating with a sufficient number of epicycles as well as with other circle-preserving devices, Ptolemy managed to provide a model of the universe that, somehow, was in accordance with the astronomical observations of the time.

During the whole medieval period, Ptolemy's geometric descriptions of the universe dominated thinking in the Western world. The Catholic Church declared this description to be in accordance with religious belief, such that by reference to the Bible, one could demonstrate that the earth was positioned in the center of the universe.

Observations of the movements of the planets became more and more precise, requiring that the geocentric model of the universe needed further geometrical adjustments by way of increasing the number of epicycles. After more than a thousand years of adjustments, the Ptolemaic earth-in-center

world model lost all traces of elegance and simplicity and became somewhat of a geometrical monster of complexity.

It was only when *On the Revolutions of the Heavenly Sphere* (*De Revolutionibus Orbium Coelestium*) by Nicolaus Copernicus (1473–1543) was published in 1543 that a new geometric description of the universe was presented in an elaborated format. Copernicus was a superb geometrician, and he showed that by locating the sun in the center of the universe and the earth and planets in circles around the sun, he could considerably reduce the number of epicycles necessary for making the model fit the astronomic observations.

To place the sun in the center of the universe was a heretical act in the eyes of the Christian church. *On the Revolutions of the Heavenly Sphere* was in preparation for a very long time, and it was only when Copernicus was lying on his deathbed that the book was published. It contained a preface by *Andreas Osiander*, who explained that the model was only intended for facilitating calendar calculations, and not meant as an exposition of how the universe is in fact operating. Copernicus's model was more precise than any previous geometric model applied to heavenly bodies. However, it is doubtful whether Copernicus interpreted his model in the way Osiander indicated; he very likely had found that the sun was in fact positioned in the center of the universe, and this soon became the general interpretation of the message from *On the Revolutions of the Heavenly Sphere*.

Johannes Kepler (1571–1630) was deeply inspired by Copernicus but also troubled by the missing fit between Copernicus's heliocentric world model and the more accurate astronomic observations that Kepler had access to. For more than 10 years, he studied the movement of the planet Mercury, and he reached the conclusion that it did not move around the sun in a circle but rather in an ellipse. This was yet one more heretical thought, because Aristotelian cosmology, as adhered to by Catholic dogmatism, assumed heavenly movements to be circular. Formulating alternatives to this taken-for-granted assumption was a dangerous undertaking, which could lead to the person facing the Inquisition. The Inquisition was a powerful institution in the Catholic Church that operated with ruthlessness in its efforts to eliminate heretical thinking—the use of torture being one such possibility.

Kepler not only formulated the idea that the planets move around the sun in ellipses; he also formulated three laws specifying the nature of the movements. These formulations have become an example of the first clear signs of scientific reasoning entering our worldview. But in a strong concordance with the Pythagorean tradition, Kepler also presented the idea that the movements of the planets created musical harmonies. In addition, he elaborated on the distances between the sun and the different planets, and for doing so he made use of the Platonic solids. In Kepler's cosmology, these geometric figures were nested within each other. This highlights the endurance of the Platonic–Euclidean tradition of understanding geometry; as shown earlier in this entry, these Platonic bodies were addressed by the last (and most important) theorem of the *Elements*.

Galileo Galilei (1564–1642) was dedicated to the heliocentric worldview, and as a consequence he twice had to face the Inquisition. He did not insist on his view, even though the legend tells that at the end of the process, in 1633, he added in a low voice, referring to the earth: “*And yet it moves.*” Galilei was punished, but only moderately by having to stay confined to his home.

Like many of the people who contributed to the scientific revolution, Galilei also shared many medieval ideas. He drew up a horoscope for many people, and when young he impressed the Florence Academy by demonstrating how the size of hell, as described by the poet Dante Alighieri, could be calculated. According to Galilei, hell had the volume of $1/12$ of the volume of the earth, and the shape of a cone with its top placed in the center of the earth, while the bottom circle of the cone had Jerusalem as its center. Geometry has indeed had many purposes beyond *measuring the earth*.

A Mechanical Worldview

The Scientific Revolution had been in progress for around 100 years, and still a range of questions were left unanswered. If the earth is spinning around itself, taking one turn per day, the speed of its surface must be enormous. How would a bird, leaving its nest in a tree, ever be able catch up with the nest again considering the enormous speed of the tree?

It was also a mystery to explain the very movements of the earth and the planets around the sun.

René Descartes (1696–1650) introduced the idea that there exist some enormous whirls, or vortices, which cause the rotations. In suggesting such an explanation, he tried to observe a strictly mechanical outlook. The first mechanical clockwork mechanism driven by a spring had been presented in 1430, and its mechanism became paradigmatic for how nature was operating. In order to explain the movement of something, one needed to identify the mechanical connections that brought the movement into play. Cogwheels need to interact directly; if a wheel were missing, nothing moved. It was by establishing such a mechanical worldview that Descartes proposed his vortex theory, suggesting the existence of gigantic interplanetary whirlpools, or vortices.

Isaac Newton (1642–1727) provided explanations of heavenly movements of a quite different nature. In manuscripts from 1669, 1671, and 1676, he outlined the principal ideas of the differential and integral calculus. However, when in 1687, he published *Mathematical Principles of Natural Philosophy* (*Philosophiæ Naturalis Principia Mathematica*), often referred to as the *Principia*, he did not make use of this mathematical insight. Instead, he carefully followed the Euclidian tradition. He started out by providing some definitions, and then he presented three laws of motion, which functioned as axioms for the subsequent deductions. From these axioms he deduced a range of theorems, including Kepler's laws for the movements of the planets. In the process of deduction, he did use geometric reasoning in a similar way as Euclid deduced his theorems. The *Principia* is carefully structured according to the Euclidian paradigm and in this way shows how the geometrical approach influenced many other areas of science centuries later.

With the *Principia*, Newton provided a new insight into nature. Since Aristotle it had been assumed that there exist two sets of natural laws, one set applicable to movements on the earth and another set applicable to heavenly movements. Newton made clear that the same set of laws are operating throughout the universe. According to Newton, the whole universe is operating as a unified mechanical system.

By operating with the notion of gravity, an attraction between physical bodies, Newton went beyond the clockwork mechanical worldview. The

idea of the existence of an attraction between physical bodies operating across the empty space is not consistent with any mechanical idea; rather it appears to be a spiritual idea, and hence it can be conceptualized as such.

Newton was a deeply religious person, spending as much time studying the Bible as for studying physics. Furthermore, Newton was attracted by different mystical movements, one being hermeticism, which might have prepared him for assuming the existence of an attraction operating across empty space. Whatever degree of mysticism that might be included in the formulation of the idea of gravity, it was to become an integral part of the mechanical worldview. However, with reference to the *Principia* the notion *mechanical* is not to be interpreted in a straightforward clockwork-like physical sense, but rather in a mathematical sense. The mechanisms defined through the natural laws are ensured through operations that can be specified mathematical but not physically.

The mathematical-mechanical worldview soon became generally celebrated in the scientific communities. It became assumed that Newton had identified the mechanism of nature, and that after Newton only some refinements of the theory were needed. As mentioned earlier, Newton's *Principia* methodologically follows the structure of Euclid's *Elements*, and one can see Newton's achievements as an almost universal extrapolation of the Euclidian paradigm.

Geometries of Empty Space

In *The Geometry* (*La Géométrie*) published in 1637, Descartes presented the basic ideas of analytic geometry. His presentation was not in any way systematic, and in *The Geometry* one does not find a straightforward presentation of a coordinate system, but it is certainly lurking behind the curtains. In any event, Descartes showed the analytic power of associating geometric figures to algebraic expressions.

Rooted in analytic geometry, the more modern version of a mathematical worldview entered the human imagination. One can imagine a three-dimensional coordinate system containing the whole universe, and the dynamics of objects in the universe can be represented by algebraic expressions—linear and differential equations in

all their complexity. On this basis, one can look into the future by means of explicit calculations, and one can read the past by similar calculations. The idea that the whole universe operates as a unified and deterministic machine achieved a sharper formulation by means of analytic geometry.

To begin with, it was accepted as a given that the universal space was a Euclidian space, in the sense that Euclidian geometry including all its possible theorems would be valid with respect to our physical space—maybe not valid with exactness as in the world of ideas, but with sufficient approximation. It was taken as axiomatic that the universe was a three-dimensional Euclidian space, a view that became so enduring that perceiving an alternative was almost heretical. Would it be possible to imagine the existence of a non-Euclidian space?

This question of an alternative to the Euclidean paradigm brings us back to the fifth axiom in the *Elements*. While the first four axioms appear simple and intuitively clear, the fifth axiom looks far more complex. One could consider the idea to instead transform the fifth axiom into a theorem? After Euclid, many attempts at proving the fifth axiom were carried out. One strategy was to formulate a negation of the fifth axiom, and then to make deductions from this negation and the four other axioms until a contradiction would appear. Certainly, strange consequences were deduced, and several times it was concluded that the fifth axiom was proved. However, only in the beginning of the 19th century was it fully recognized that the strange consequences were indeed not contradictions but theorems in a non-Euclidean geometry.

There now exist several different forms of non-Euclidean geometry. One can negate the fifth axiom by assuming that there does not exist any parallel line going through a point outside a given line. This leads to what is called *elliptic non-Euclidean geometry*. One can also assume that there exist more than one parallel line going through a point outside a given line. This leads to what is called *hyperbolic non-Euclidean geometry*. It was the elliptic version that Albert Einstein used when formulating the theory of relativity. In this way, he described the universal space as being non-Euclidean and by doing so established a profound paradigmatic shift in our conception of nature. With these remarks, however, we have moved far beyond classical geometry, whose roots

nonetheless still play a significant role in our perception of reality and space.

Four Dimensions of a Philosophy of Geometry

In the book *Connecting Humans to Equations: A Reinterpretation of the Philosophy of Mathematics*, Ole Ravn and Ole Skovmose suggest that a philosophy of mathematics operates with four dimensions in being ready to address ontological, epistemological, sociological, and ethical issue. Let us now explore these four dimensions with respect to geometry, and in this way reflect on the presentation of classic geometry that appears in the previous sections.

Ontology concerns what is assumed to exist, and with respect to geometry it raises questions like: What is a point? What is a line? What is a plane? And more generally: What is the nature of geometric entities? The Pythagoreans claimed that numbers had a real and independent existence from human beings, and that the world was composed of number units. This audacious ontological claim was challenged by the discovery of irrationalities. Plato redirected the ontological discussion by inventing a world of ideas that hosted geometric and other mathematical entities in a realm of their own.

A more modern and nihilistic ontological account of geometry is found in Hilbert's *Foundations of Geometry*, first published in German in 1899. At that time, several mathematicians had expressed doubt about the validity of the deductions presented in the *Elements*. It was pointed out that Euclid, when proving the theorems, had used a range of implicit assumptions besides the explicit formulated five axioms. In the *Foundations of Geometry*, Hilbert made a reformulation of the start of Euclidian geometry by presenting not five but 20 axioms. This completed system represents a kind of perfection of the *Elements* and it goes to show again one final time that the impact of Euclid's geometry on all later geometries cannot be overstated.

As a consequence of this perfection, Hilbert could announce that for proving geometric theorems the nature of notions like point, line, and plane are irrelevant. The only thing that counts in geometry is the interrelationships between these

entities as stated in the axioms. Instead of points, lines, and planes, one could as well talk about beer mugs, tables, and chairs. By making this claim, Hilbert presents the ontological issue as being irrelevant to geometry. As part of the broader formalist program in mathematics, as Hilbert later advocated, ontological issues are irrelevant not only to geometry but to mathematics in general.

Epistemological issues concern how we obtain geometric knowledge. One common sense idea would be that such knowledge is based on empirical observations. However, the Euclidean paradigm sets a specific epistemic standard: geometric knowledge is built upon self-evident axioms, and from these axioms one deduces consequences. The logical nature of the deductions ensures that if the premises are true, then the consequences will be true as well. Because the axioms are chosen in such a way that their truths can be grasped immediately, truths will flow from the axioms throughout the whole deductive system and ensure the truth of each and every theorem.

This epistemic paradigm came to dominate, and it was assumed that not only geometric knowledge but knowledge in general should be developed according to this deductive pattern. In the *Principia*, Newton followed this pattern; however, it was applied far beyond mathematics and the natural sciences. In his *Ethics*, Baruch Spinoza (1632–1677) presents a theory of ethics, including a range of statements concerning how to behave. The *Ethics* starts with definitions, followed by one axioms, and from these Spinoza deduces theorem after theorem, which constitutes his theory of ethics.

By the *sociological* dimension of a philosophy of geometry, we have in mind reflections about how social factors have an impact on how geometry is formulated and perceived. One such factor is Eurocentrism. Eurocentrism in its general format has been explored by Martin Bernal in *Black Athena: Afroasiatic Roots of Classical Civilization*, and with particular reference to mathematics by George Gheverghese Joseph in *The Crest of the Peacock: The Non-European Roots of Mathematics*.

The formulation of the modern worldview took place during the period where the process of brutal colonizations was in full development, and the slave trade turned into a widespread business. These processes integrated different versions of racism as part of the common outlook in the West.

Slavery had existed throughout all historical periods, but as part of the modern outlook the idea developed that some groups of people were naturally born to be enslaved. Compared with White people, Black people and people from Asia, the Pacific, and the Americas were held to be inferior.

This outlook also had implications for how the origin of geometric thinking was interpreted. In keeping with the modern, Eurocentric perspective, it was difficult to acknowledge that geometric knowledge could emerge in the East or in Africa. And because such knowledge evidently had been developed in these places even earlier than in the European sphere, so it was argued that those were only preliminary versions of proper geometry. Such versions, it was claimed, were based on empirical insights rather than on deductive patterns, and that only when Euclid brought together the *Elements* did geometry find its proper and sublime form.

To support the claim that geometry was a Western achievement, Greek culture was interpreted as belonging to the West, and its connections to the East and to Africa were downplayed. The Eurocentric interpretation of the history of geometry and of mathematics in general became an integral part of the modern outlook and has remained dominant right up to the present time.

By the *ethical* dimension of a philosophy of geometry, we refer to reflections on the social impact that might be exercised through geometry. Let us start considering an ideological and meta-physical impact. Cosmologies have been formulated through geometry, and paradigmatic elements of the Euclidean formulation of geometry have been defining parts of such worldviews.

Euclid considered only circles and straight lines as being the basic geometric entities, and certainly not any spirals. As we saw, such paradigmatic assumptions had a huge influence on the way Ptolemy elaborated on his geocentric worldview. What other kind of movements could be considered? It was not until the time of Kepler before it was possible to question this deep impact of the Euclidean paradigm when thinking about nature.

However, geometry is enlisted in developing not only metaphysical but also physical constructions. If we pay less attention to Euclid's presentation in the *Elements* but look at geometry as applied in architecture and in engineering by means of descriptive geometry, we see powerful achievements completely

based on geometric insight. Geometry is an integral part of three-dimensional simulations of possible new constructions, whether it be it a tunnel, an airport terminal, or a car model. Three-dimensional simulations are also used in medicine, where, for example, robots can assist in performing surgery. Similar simulations also constitute an integral part of modern war technology as, for instance, in the development of guided missiles that can cross vast distances in search of their targets.

In conclusion, this entry has shown that geometry can be brought into action within many different contexts. Any such actions are in need of critical thinking about the reasoning behind them and the values imbued in these actions. Geometry in action calls for ethical reflection.

GEOMETRY, NON-EUCLIDEAN

Other than the geometry described in the *Elements* of the ancient Greek mathematician Euclid (born c. 300 B.C.E.), the first geometry that could be capable of describing physical space was

proposed in the 1830s independently by Nikolai Lobachevskii in Russia and János Bolyai in Hungary. When it was eventually accepted in the 1850s and 1860s as a valid piece of mathematics, after its having being reworked by Carl Friedrich Gauss, Bernhard Riemann, and Eugenio Beltrami, it provoked a widespread revision of ideas about what constitutes a geometry, and by 1900 a revision of, and return to, axiomatic methods in mathematics. Its consequences also forced a rethinking of the relation of geometry to physics, and in that sense it is a progenitor of the general theory of relativity, later proposed by Albert Einstein.

Background and Origins

By the year 1800 Euclidean geometry, as described in any of several different editions of Euclid's *Elements*, was taken to be the bedrock of mathematics, along with elementary arithmetic and some simple algebra. For many educators, it was also taken to be an exemplary display of human reasoning that established, through rigorous thought alone, a true description of the universe around us, the space for Isaac Newton's celestial mechanics that he had called *God's sensorium*. Eminent philosophers such as John Locke, David Hume, and Immanuel Kant treated it as such, and even though René Descartes had proposed a different approach to geometry, he did not differ in his conclusions.

Over the course of the two millennia since it was written, commentators and editors in Greek, Islamic, medieval, and modern European traditions had found small faults with Euclid's *Elements* that they enjoyed patching up. They agreed that it was austere—it did not make clear how you might come to similar results in geometry yourself—and indeed that there were one or two substantial difficulties in the text. One, with which we shall not be concerned here, concerned the nature of irrational numbers. The other was the much-discussed matter of the parallel postulate, and that proved to be the fatal flaw in the *Elements* and the way in to other geometries entirely.

In the *Elements*, Euclid showed that in a triangle any two angles have a sum less than π . What then, of the converse case: If two lines cross a third and the angles where they cross sum to less than π , do the two lines meet, and the three lines

form a triangle? Euclid made the explicit assumption that they do, and this is the parallel postulate, and the fifth and final of his postulates in all modern editions. It has the immediate consequence that if the two lines cross a third and the angles they make sum to π , then the two lines are parallel, which is why the postulate acquired its name.

The parallel postulate is immensely useful. Once it is introduced in the *Elements*, Euclid shows that the angles sum of any triangle is π , proved that parallel lines are equidistant, and established the Pythagorean theorem. The postulate may be obscurely expressed, but the idea that there are parallel lines is highly intuitive although, unlike the other postulates, it is less than empirically certain. It is easy to show that if the angles sum to something very little less than π then the two lines will meet very far away, well beyond our galaxy. Accordingly, a tradition grew up, starting in Greek times, of attempting to prove the parallel postulate on the basis of all the other assumptions Euclid had made.

By 1800, there was a growing literature of this kind, all of it unsuccessful. The best results, many known to mathematicians of the Islamic world, only showed that, given the rest of the *Elements*, the parallel postulate was equivalent to the assumption that the sum of the angles in a triangle is π , to the assumption that parallel lines are equidistant, and to the assumption that there are similar figures, or scale copies, that are not congruent (triangles whose angles agree in pairs but whose corresponding sides are of different sizes). Euclid's assumption looked more and more sensible on pragmatic grounds—imagine a geometry in which these results are all false—but it irked some of the best mathematicians that they could not prove such an apparently obvious truth.

Three exceptions stand out. The first is the Jesuit priest Gerolamo Saccheri, who published a book in Latin in 1733, the year he died, entitled *Euclid Freed From Every Flaw*. In it tried to show that the sum of the angles in a triangle must be π by showing that any alternative was self-contradictory. He speedily showed that assuming there are triangles with an angle sum greater than π contradicted other results in the *Elements*. Then he set to work on the assumption that there might be triangles with an angle sum less than π , and he found many interesting consequences. Finally, he

claimed to have found the contradiction he sought, in what happens when two lines cross at infinity, but rightly no-one was persuaded.

The second exception is that of the Swiss mathematician and polymath Johann Heinrich Lambert (1728–1777), who wrote up an account very similar to Saccheri's but stopping short of the final claim. Instead, he said that the nature of a straight line needed to be better defined. He would be willing to agree as a matter of fact that they behaved as Euclid said they did, but he did not see why they had to do so as a matter of logic. Lambert was thus the first person to hold out the possibility that there might be another geometry that agreed in every respect with Euclidean geometry except with regard to straight lines. However, he did not publish these investigations—they were published only after his death—and he left the many theorems he had established on the assumption that the angle sum of a triangle is less than π as tantalizing indications of what a new geometry might be like. For example, the area of a triangle is proportional to π minus its angle sum.

The third exception is Gauss. In 1801, the year he turned 24, Gauss was about to establish himself as the leading number theorist and an important astronomer, and his reputation only grew after that. He entirely reformulated several branches of mathematics and opened up others, and by an accident of when he was born there was no one else like him for perhaps 20 years. The paradox in the story of non-Euclidean geometry is that Gauss published nothing on it and contented himself with a few hints in book reviews. Only after his death in 1855 was it discovered how much he had known, and even that is problematic. Still, what he did write down showed that he was doubtful that the truth of Euclidean geometry could be proved.

The Discovery of a New Geometry

Honor for the discovery of non-Euclidean geometry is famously divided between the Russian mathematician Nicolai Lobachevskii (1792–1856) and the Hungarian mathematician János Bolyai (1802–1860). Bolyai's father, Farkas Bolyai, was also a mathematician; indeed he had studied mathematics at Göttingen with Gauss, and he had picked up the bug of trying to vindicate the *Elements*, but without success. When his

son turned out to be something of a prodigy, Farkas tried to discourage him from following him, saying he had wasted his life in this work, but János did not listen. When he found that trying to defend Euclid ended in failure, however, he decided to try the opposite and explore a new geometry instead. In 1831, he published his insights in a 24-page Appendix to his father's two-volume book on geometry.

Lobachevskii's route into the subject was much the same. Finding nothing wrong with forming a different understanding of straight lines, he decided around 1829 to accept the implications of proceeding on the assumption that his new theory could also be coherent and even true. He published long articles in Russian, an article in French in the main German journal of mathematics, a short booklet in German, and toward the end of his life a book in French on the new geometry and its implications.

Both Lobachevskii and János Bolyai published strikingly similar results, so it is convenient to describe the work of just one, and Lobachevskii's is easier, so let us briefly describe it here. In plane geometry, the parallel postulate is equivalent to the statement that given a line ℓ and a point P not on ℓ there is exactly one line through P that does not meet ℓ . Lobachevskii investigated the idea that instead there might be two lines through P , one in each direction, that approach the line ℓ arbitrarily closely but do not meet it (this means that there are infinitely many lines through P that never meet ℓ , and are sometimes said to be ultra-parallel to it). The two lines that approach ℓ arbitrarily closely Lobachevskii called the parallels to ℓ through P , and they make an angle with the perpendicular from P to ℓ that depends on the length of that perpendicular: the further P is away from ℓ , the smaller the angle. Lobachevskii called this angle the angle of parallelism and regarded the length of the perpendicular as a function of the angle. By an ingenious argument he found an explicit expression for it, and by more work he found formulae connecting the sides and angles of triangles in the new geometry as a result.

These formulae bore a striking resemblance to the formulae of spherical trigonometry, which describe the geometry of a spherical Earth, and were well known to every land surveyor and map maker. Where the spherical trigonometrical formulae have sines and cosines, Lobachevskii's have hyperbolic sines and cosines (and the occasional

change of sign, as these functions require). Lobachevskii could deduce many things from these formulae. For example, very small triangles will have angle sums that are only just less than π , and so are virtually indistinguishable from Euclidean ones. This partly explains why the new geometry had gone undetected hitherto, but it also says that any test of the truth of the new geometry would have to involve astronomical measurements (very large triangles must have angle sums noticeably less than π). He suggested one such test but was unable to carry it out. The very existence of the formulae strongly suggests that the new geometry is logically sound, but Lobachevskii's derivation of them did something else. It involved working in three dimensions, and so what he proposed really could be a geometry of space.

The reception of the work of Lobachevskii and Bolyai was appalling. It was met with silence or ridicule. In Lobachevskii's case, Gauss moved to get him accepted by the Learned Society of Göttingen, but otherwise did nothing to promote his ideas other than by writing a few letters to a colleague. János Bolyai fared worse. His father sent Gauss a copy of his book, and Gauss replied to say that he knew all that János had done already, and even demonstrated a better proof of one or two of the younger man's results. János was so angry he refused ever to publish again, which naturally did not help him win the credit that was his due. Eventually, he learned of Lobachevskii's work, and was pleased both to see it and to see what he had done that Lobachevskii had not, but that was all.

The case of Gauss's reaction is even stranger. By 1831, he had indeed come to such an understanding of new two-dimensional geometry that he could say he knew all about it, and to have no doubt in his mind that it made coherent mathematical sense. Therefore, he could say that he no longer thought that Euclid's was the only possible plane geometry. But he had not investigated the three-dimensional case, as Bolyai and Lobachevskii had done, and could only say that he doubted the uniqueness of Euclid's geometry in that case, not that he had shown it to be false.

What is even stranger, is that, unlike Bolyai and Lobachevskii, Gauss did possess compelling grounds for asserting the new geometry. They had merely explored the consequences of a new definition of parallelism, they had no proof that a

contradiction did not lurk in what they had begun to explore. This greater degree of confidence came from his work on the theory of surfaces.

In the 1820s, Gauss had taken on the task of surveying the lands of Hanover and southern Denmark, and, physically and mentally demanding as that work was, he found himself led to recast the theory of surfaces. Eighteenth-century mathematicians knew some surfaces, such as the sphere and the generalizations of the ellipse, parabola, and hyperbola, but they tended to think of a surface as the surface of something, like the peel of an apple. Gauss took the view that a surface was something described by two coordinates, such as longitude and latitude on the sphere. If we take x , y , and z , axes in space, then every point on the sphere has its x , y , and z coordinates with respect to those axes, and each of x , y , and z is a function of the two latitude and longitude coordinates. Gauss now decided that a surface was anything whose x , y , and z coordinates each depend on two quantities, which we may call u and v .

Perhaps the most obvious fact about most surfaces is that they are curved. Some are curved like bowls, some are curved like saddles, some surfaces are bowl-shaped in one region and saddle-shaped in another. Gauss discovered a result so exceptional he called it an *exceptional theorem*, and as so often he was right: Its full meaning was to reshape geometry. It involves little more than the Pythagorean theorem to discover that the distance between nearby points on a surface is given by a simple formula involving three functions of the coordinates u and v , which Gauss called E , F , and G . This formula has become known as a metric. What Gauss found was that exactly how curved a surface is at a point is given by another function of the three functions E , F , and G . A complicated one, to be sure, but a formula that involves those three functions of the coordinates, and does not involve x , y , or z . This means it is intrinsic, it depends on the coordinates alone. Put anthropomorphically, two-dimensional creatures living in the surface could discover how curved the surface was without ever leaving the surface.

What has this to do with non-Euclidean geometry? At some stage in the late 1830s, Gauss discovered that the trigonometrical formulae of Bolyai and Lobachevskii could be derived from his theory of curvature, specifically for triangles

on a saddle-shaped surface of constant negative curvature. However, he did not publish this result, nor did he generalize it to three dimensions. What he knew about the new geometry was only found in his desk drawers after his death in 1855, and such was his status it changed the perception of the new geometry utterly.

It's not clear why Gauss did not publish it, and he left splendid discoveries on other subjects unpublished too, but one reason may well have been that he felt uncomfortable about it. Not about the correctness of his work, so much as the controversy it would cause. Overall, the main reason for the rejection of the work of Lobachevskii is that it ran into an orthodoxy upon which everyone from the best philosophers to the humblest schoolteacher had accepted all their lives: the validity of Euclidean geometry. Yes, the new ideas were hard to understand; yes, they were not logically compelling—but they were not contested on those grounds. They were not contested at all. A leading Russian mathematician wrote that Lobachevskii was barely fit to be a schoolteacher, and most mathematicians simply ignored his work. Only the name of Gauss made people rethink.

The Acceptance of Non-Euclidean Geometry

As it happens, the year before he died Gauss examined the post-doctoral thesis of the mathematician who did most to pick up these ideas and make compelling sense of them: Bernhard Riemann (1826–1866). As part of the work he undertook for his postdoctoral qualification, Riemann took Gauss's ideas about the geometry of surfaces and extended them to any number of dimensions. This included showing that in every dimension greater than one, a metric and an intrinsic curvature at a point can be defined. He also emphasized that any set of points with a metric is a geometry and does not need to be a subset of any other space: One simply works with the coordinates and quantities that depend on them.

What then of Euclidean geometry? It becomes just one geometry among many, distinguished by being, in each dimension, the simplest geometry with zero curvature. In two dimensions, there are many geometries with zero curvature, of which the plane and the cylinder are two examples, and

spaces whose curvatures are the same at corresponding points are locally the same; which is why old-fashioned printing worked.

By the same token, non-Euclidean geometry in each dimension is a geometry of constant negative curvature, and Riemann wrote down an appropriate metric in each case that takes a disc of that dimension and radius 1 and exhibits it as a space of constant negative curvature. But does this mean it exists? To Riemann; to Eugenio Beltrami (1835–1900), the Italian mathematician who closely followed him; to Felix Klein (1849–1925), the leading German geometer after Riemann's death; and very soon to the French mathematician Henri Poincaré (1854–1912), who made innovative use of the geometry in another branch of mathematics entirely, the answer was a simple Yes. It is an entirely self-consistent description of a geometry, and nothing more need be asked of it.

What Riemann's work did not do was show that a surface with two-dimensional non-Euclidean geometry exists as a surface in ordinary Euclidean three-dimensional geometry with the same sense of distance between its points in each case. This is unlike the familiar sphere, which is the canonical example of a geometry of constant positive curvature. Riemann, following Gauss's lead, separated the question of the existence of a geometry into two parts: the first concerns the existence of a self-consistent space (nothing more than a set of points) with a definition of the distance between those points; the second concerns the question of whether that space can be embedded in another space (say a Euclidean space) without altering the distances between points. A space of constant positive curvature can be embedded in a Euclidean space of one dimension higher; a space of constant negative curvature cannot be embedded in a Euclidean space of one dimension higher—but that is no reason to say it does not exist as a mathematical object.

The simplest description of non-Euclidean two-dimensional geometry is known as the *Poincaré disc* (Figure 1). It is a map or picture of the geometry onto the points inside a circle of radius 1. The geodesics appear as arcs of circles perpendicular to the circle that bounds the disc, and angles are represented correctly, while a simple formula describes how sizes of figures appear to shrink as they are moved away from the center.

Figure 1 The Poincaré Disc Model of Non-Euclidean Geometry. All These Triangles Are Congruent, and All Their Side Arcs Are Geodesics

Source: Wikimedia Commons. Image is in the public domain.

All the seemingly paradoxical results of Saccheri and Lambert, and the definitions and theorems of Bolyai and Lobachevskii, are well displayed in the disc with a non-Euclidean metric.

What to make of all the failed attempts to exhibit a non-Euclidean geometry before Riemann? They were trying to find the appropriate surface as a subset of three-dimensional Euclidean space, and another German mathematician, David Hilbert (1862–1943), was to show in 1902 that under very modest restrictions this cannot be done.

Of course, the geometry on the sphere is also not Euclid's, and it worth observing why all the efforts to prove that Euclid's geometry was the only true geometry did not simply halt with the example of the sphere. The reason is that it departs from Euclidean geometry in two ways, not just the parallel postulate but because it is a finite space. It fails the parallel postulate because geodesics (the curves of shortest length between their points) on the sphere are great circles, and any two meet, so there are no parallels. It is finite in the sense that every geodesic on the sphere is of finite length (the circumference of the sphere) and Euclid had assumed that lines are indefinitely extendible. But spherical geometry is, nonetheless, a geometry different from Euclid's, and the reason it was never proposed in the context of a search for a non-Euclidean geometry is that, even if only tacitly, the search was for a non-Euclidean geometry that could be a geometry of physical space. For as long as it was taken for granted that space was infinite, the sphere was not a candidate. Happily, the disc

with Riemann's metric on it does have infinitely long geodesics.

Philosophers were reluctant to accept non-Euclidean geometry, especially if they were in some measure followers of Immanuel Kant. Kant had used the proof that the angle sum of a triangle is π (which uses parallel lines) as an indication of how mathematicians make constructions in order to go beyond the bare definition of mathematical objects. Various attempts were made to claim that the new ideas only established some logical result but could not make claims to be knowledge of the world, but these all lacked conviction. Gottlob Frege (1848–1925), the brilliant German logician who had trained as a mathematician, simply refused to accept non-Euclidean geometry on the singularly weak grounds that there was only one physical space and we know how to talk truly about it.

Implications for the Truth of Mathematics

Around 1900, the educated general public caught up with the new geometry and naturally wondered whether it or Euclid's geometry was true. Poincaré gave the most intriguing answer, which was that we could never know. Not because any measurements might be too delicate, but because it would be a matter of convention. Suppose you measured the angles of a large triangle whose sides are rays of light and found the sum to be less than π . There are, he said, two interpretations. One is that space is non-Euclidean and light rays are straight or geodesic, the other is that space is Euclidean and the path of a ray of light is not straight, and there is no logical way of deciding between the two. It is decided by convention among the interested parties, and simplicity will be a guide. The Poincaré disc description can be interpreted as saying that the disc displays non-Euclidean geometry and figures only appear to shrink, or that the disc displays Euclidean geometry and the figures are cooling down and shrinking. Again, Poincaré refused to say that one description was correct, but the Italian geometer Federigo Enriques (1871–1946) was among those who said that because we could not change the temperature of the disc at any point there was only one interpretation: the disc displayed a hypothetical property of space. Poincaré, however, extended his conventionalist view to any set of

circumstances where purely mathematical terms are applied to physical objects and systems and gave reasons for why we would always choose the ones that gave us the simplest theories.

The last decades of the 19th century saw an abundance of work on Riemann's rather cryptic presentation of his ideas. What gave them salience in the 20th century was Einstein's realization that the force of gravity could be understood in terms of its geodesics. This meant that it would be possible to interpret gravity as a curvature of space (more precisely, of space-time). Almost as soon as Einstein published these ideas, with the help of his mathematically better-educated friend Marcel Grossmann, another German mathematician, Karl Schwarzschild, showed that it was possible to exhibit a mathematical space that satisfied the equations Einstein and Grossmann had obtained, and the subject of cosmology was born. With the revival of cosmology after the Second World War, attention has focused on extremely massive objects which curve the space-time around them, and give it some form of positive curvature, but it is unlikely this work would have been done without the discovery of the first physically plausible non-Euclidean geometry.

The example of hyperbolic geometry did more than this. It showed that there had been something wrong all along with those claims that Euclidean geometry was true, and that a few self-evident axioms described the universe. It broke that endeavor into two: find a self-consistent mathematical system and investigate a problem about the world with an eye to seeing if some geometry is present. For a time, this even discredited the idea of starting with axioms at all. Riemann spoke only of hypotheses at the foundations of geometry, and disparaged axioms, but a generation later Hilbert showed how to give a rigorous axiomatization of plane geometry, and then of non-Euclidean geometry, and indeed of several other plane geometries that did not fit Riemann's metrical approach at all. In so doing, he established the idea that one can write down a system of axioms, check it for self-consistency, and then study any system of objects that obey the axioms. The axioms do not tell you what the objects are—they tell you how you may use them. In the same way, the rules of chess tell you how the pieces may move, but not what inner meaning they might have.

Many major branches of mathematics have since been axiomatized: much of modern algebra, geometry, topology, integration theory, probability, and others. The view became that existence in mathematics was synonymous with freedom from contradiction (a view that Frege contested in an exchange with Hilbert) and a great number of examples of resolutely pure branches of mathematics sprang up.

It would be easy to dismiss the whole enterprise as self-indulgent and unworldly, but that would be foolish. Riemann's work offered physicists a variety of universes to contemplate, and the genius of Einstein was to seize that opportunity to create his general theory of relativity. The abstract side of all of particle physics today ultimately rests on mathematically defined systems, although in the rush to understand deep physics the mathematics may well emerge in a rough and ready form.

In any case, an axiomatically defined system is one that allows you to be sure that you have not smuggled ideas into your theory that may not belong. As we enter the era of machine-checkable proofs, we can have ever-greater confidence in the validity of our arguments, which is an intriguing comparison with the much more thoroughly obscure working of machine learning and large Artificial Intelligence systems.

Hilbert defined his new geometries very often in terms of coordinates involving novel number systems, and so he began to ask about how the consistency of even the usual system of numbers can be ensured. He hoped to show that some combination of set theory and logic could do this, but in 1931 Kurt Gödel showed that any system of mathematics large enough to contain a theory of multiplication would be either inconsistent or incomplete. Inconsistency would mean any statement and its negation were simultaneously true; incomplete means that there are statements such that both they and their negations are consistent with the axioms. This means that they cannot be proved, and there are even contrived statements of this kind that are self-evidently true. Many mathematicians today are quite happy with the set of axioms known as *Zermelo-Frankel* with choice, after Abraham Frankel, who improved Ernst Zermelo's original axiomatization, and the acceptance of the Axiom of Choice, but set theorists and logicians are aware that there are many other

choices that could be made. They feel uncomfortable with the idea that the world of mathematics could be one of many things and we will never know which one is true, and they reach back to the early days of non-Euclidean geometry for an example of what it is like to lose an easy sense of the truth of mathematics.

Perhaps the ultimate lesson of the discovery of non-Euclidean geometry is that it forced mathematicians to think clearly about what geometry is about, and to come up with a coherent set of abstract ideas for it. At first, they had two systems, both in need of further rigorization, Euclid's and that of Bolyai and Lobachevskii. Then, with Riemann, they had infinitely many off-the-peg accounts of metrical geometries. Then they came up with axiomatic geometries and axiomatic systems, which needed to be checked for self-consistency, and then it emerged that the logic governing their use also needed to be made precise. This forced a remarkable degree of clarity on mathematics and a comparable reduction on the reliance on naïve intuition. But it also proposed to workers in physics, and then in other fields, a clearer sense of what a rigorously formulated theory can provide, and how it can be tested by, and even guide, experiment, and to enrich and articulate a complicated relationship between abstraction and observation that is a characteristic feature of the modern world.

GERM THEORY

The germ theory of disease is the contemporary scientific theory for causation of infectious diseases. In this theory, the central tenet is that microbial organisms (e.g., bacteria, viruses, protozoa, prions, and fungi) are the causative agents behind many diseases.

From before recorded history, infections have plagued both animals and humankind. The effects were devastating, and it was understood that when a disease appeared, social distancing or quarantine would normally cause the spread to stop. Each disease, however, brings with it a different challenge when it comes to managing and defeating an infectious outbreak. To achieve these objectives requires an understanding of the causative agent, its source, and what it takes to treat it. Throughout the centuries, and with the advent of the Enlightenment, many of these questions have been answered, at least in part. To arrive at the germ theory of disease required overcoming obstacles in understanding just what a microbe was and, until the invention of the microscope, it was nearly impossible to move from incorrect perceptions. Through the work of many scientists and physicians, we now have a working theory that has stood the test of time, with some variation, but newer ways of defining the causation of infectious diseases are ongoing.

Origins

The scientific journey to consolidate evidence that many diseases are caused by germs, or microbial organisms, has been a long one. From biblical times, where quarantine was first described in written form, evidence existed that an outside entity or force was responsible for causing disease, such as leprosy (a.k.a. Hanson's disease) or sexually transmitted diseases. The ancient Romans and Greeks also left records of infections that were contagious and matured into plagues. Between

460 and 400 B.C.E., the general and historian Thucydides documented symptoms and events surrounding the plague of Athens, which added to the death toll caused by the Peloponnesian War. At the time, though, pathogens were thought of as *seeds of disease* that caused disease. During this period, the philosopher Aristotle put forth the notion that contagious diseases were caused by spontaneous generation. Spontaneous generation suggested that organisms developed without the need for sexual reproduction and often formed from nonliving matter, such as dust. It was not understood that adult flies laid eggs on the surfaces of rotting food, which hatched into larvae (maggots). The eggs were not visible to the human eye, so it was thought that they just appeared due to some unknown force.

The idea that a common agent was causing disease began to mature during the Middle Ages after a Persian physician, Ibn Sina (Avicenna), wrote about contagious disease in his medical text, *The Canon of Medicine*. He used examples of known epidemics to teach about contagion, and the miasma theory became the accepted basis for understanding the causes of infectious diseases. The miasma theory set forth the principle that the agent responsible for causing infectious diseases was *bad air* or a form of noxious vapor that all the sick were exposed to. It was believed that a miasma could be identified by the foul odors that the infected often emitted while sick. The source of the miasma was predominantly described as being from the air, water, or food. There was no discrimination between a source that was independent of a miasma (e.g., contaminated water) and that which spread from person to person.

By the time of the Black Death, a devastating pandemic of the bubonic plague in the mid-1300s that was later understood to be caused by the spread of *Yersinia pestis*, a bacterium that is spread from fleas to rats, it became clear that there was some particle that was being spread from person to person. The information learned from the geographic spread and symptoms of the victims in this plague made it clear that direct contact was not always necessary for the spread of a contagious disease. The Italian physician Girolamo Fracastoro discussed this in his book *De Contagione et Contagiosis Morbis* in 1546.

In 1668, another Italian physician, Francesco Redi, put forth his theory to refute the cause of

infectious diseases through spontaneous generation. He employed the scientific method to perform an experiment where he placed meatloaf and egg in three separate jars; one was left open, another was sealed, and the last he covered with gauze. Within a few days, the meatloaf in the open jar was covered with maggots, while the jar covered in gauze only had maggots growing on top of the gauze. The sealed jar had no sign of maggots growing. Within that period, several more experimental results were offered to refute the validity of spontaneous generation, including those of Pier Antonio Micheli, John Needham, and Lazzaro Spallanzi, which, taken together, showed that living matter could not possibly arise spontaneously from nonliving matter. There had to be more to the appearance of microbes than random events.

More supportive information came forth during the Enlightenment (17th and 18th centuries), when the scientific method was diligently employed to answer many questions about the workings of the physical and organic world. Perhaps most influential at that time was the Dutch microscopist Antonie von Leeuwenhoek, who observed yeast cells undergoing division on a slide with foam from beer that had been fermenting. He also observed that fermentation was not possible in sterile air or with pure oxygen, which led him to realize that airborne microorganisms were responsible for the initiation of fermentation, not spontaneous generation.

Later, in 1859, a French scientist, Louis Pasteur, would suggest that microorganisms (germs) present in the body were the cause for infectious diseases and laid to rest the theory of spontaneous generation. The experiment involved boiling meat in a swan's-neck flask, which prevented particles from falling into the broth while still allowing air to enter the chamber. There was initially no growth in the flask, until the flask was turned in a fashion to allow particles to enter the chamber. Soon after the position changed, the broth became cloudy. The idea of spontaneous generation was nonetheless difficult to uproot, even with many experiments disqualifying it as a sound explanation of how microbes (and maggots) appear in different media (e.g., meat, broth).

In 1864, Joseph Lister, a professor of surgery at Glasgow University, learned of Pasteur's germ theory and determined to apply its principles to the problem of surgical infections. The cause of

surgical infections was not well understood, and patients who underwent surgical procedures often died from sepsis or gangrene. Many new innovations in the performance of surgery helped a patient endure a procedure, such as the invention of anesthetics, but infections remained a formidable obstacle to the uncomplicated healing of the postsurgical patient.

In his personal time, Lister, with the help of his wife, used his home laboratory to explore the nature of surgical infections. He introduced his hypotheses for the causes of surgical infections in clinical trials at the hospital where he trained as a surgeon. He explored ways to prevent bacteria from entering a surgical wound, using a chemical called *carbolic acid*, which he later called *an antiseptic*. In suitably dilute form, carbolic acid killed the germs on contact but did not do harm to human skin, which made it a success. Lister continued to develop antiseptic techniques during and after surgery, cleaning surgical instruments he invented, and asked his staff to use weakened carbolic acid in their hand washes before working in the operating arena. He also sprayed carbolic acid in the air around the patient to kill any airborne bacteria. His ultimate test was using his new techniques to perform surgery on Queen Victoria. The incidence of surgical infections plummeted after surgeons began implementing his new techniques. Even then germ theory was slow to be picked up by pockets of scientists who still endorsed spontaneous generation.

After Lister had provided a large body of evidence that supported the germ theory, a German physician named Robert Koch expanded on this work. He published a paper in 1876 that demonstrated that a bacteria named *Bacillus anthracis* was the causative pathogen for anthrax. A few years later, he followed that discovery with showing that *Mycobacterium tuberculosis* was the causative agent of tuberculosis and *Vibrio cholerae* caused the disease cholera. In the case of cholera, Lister developed public health measures to control outbreaks of the disease. Through his experiments, he devised a list of criteria that seeks to prove causation of an infectious disease, since called *Koch's postulates*. These criteria include: (1) A suspected microorganism must be present in a diseased individual, not a healthy one; (2) the microbe has to be cultured from a diseased individual; (3) inoculation of the isolated microbe

must cause disease in a healthy individual; and (4) the same microbe must be isolated from the inoculated, diseased individual. Additionally, Koch introduced using dry heat and steam sterilization to the arsenal of methods to kill harmful microbes.

Germ Theory Denialism

During the period when Pasteur's germ theory began to gain traction, another scientist, Antoine Bechamp, a chemist and pharmacologist, put forth his theory of the cause of infectious diseases, *pleomorphism*. Pleomorphism stated that a microorganism goes through various stages during its life cycle and can develop into a bacteria, virus, yeast, or fungi, directed by environmental forces. This theory was also supported by Günther Enderlein, a German zoologist and physician. Ten years of experimentation led Bechamp to conclude that molecular granulations he called *microzymas*, which are present on the cells of plants and animals, were responsible for manifestation of infectious diseases. What differs between germ theory and pleomorphism was that germ theory focused on disease being caused by external factors, while pleomorphism pointed to the internal environment. Pleomorphism has since been disqualified as a plausible theory.

Koch's Postulates Today

The underlying tenets of Koch's postulates are still widely used today. However, after the advent of the field of virology, some modification to the criteria needed to be made. For one, it was later determined that there are some microorganisms that cannot grow in cell-free culture, such as viruses and obligate intracellular bacteria. Owing to this type of exception, other avenues of infection cannot be dismissed by the Koch's postulates criteria.

To address these variances in presentation, molecular biology has been brought in to determine whether a pathogen is present to cause a disease. For example, polymerase chain reaction is used in clinical settings for sequence-based identification of viruses and bacteria. There are now whole sequencing libraries of viruses, bacteria, and large parasites for reference. This brings to light the fact that as technology advances, so will the need to modify Koch's postulates to help determine a pathogen's role in causation. When

disease is expressed in one animal model, it does not always lead to the same disease in another animal model. For example, when a bacillus gene that causes the plague is given to *Caenorhabditis elegans*, it causes death, but when introduced to a mouse model, death does not occur. Without the knowledge that disease can be species-specific, or the newer epidemiological understanding that some species are just carriers of a disease (reservoirs) while others get sick with the disease, outcomes like the mouse model would lead to failure of Koch's postulates.

In fact, in emerging zoonoses (infections that are transmitted from animal to human), the pathway of infection can be difficult to fit into Koch's postulates. When it was observed that some viruses, such as Ebola, Sin Nombre, and Middle East Respiratory Syndrome coronavirus, do not cause disease in their natural host, but then produce a severe or deadly hyperinflammatory response in a new host, it was clear that a modified version of Koch's postulates was needed. Sometimes, infected hosts are asymptomatic, so it is difficult to apply the criteria for a diseased individual when it appears no disease is present. This is an important reason to utilize genetic sequencing to determine the presence of a virus in symptomatic and asymptomatic scenarios. Using this method is supported by contact tracing in individuals or animals where a known contact has occurred and there is a mixture of disease expression and sequence-verified presence of a virus.

To address some of these discrepancies with fulfilling Koch's postulates, newer models have been instituted that incorporate Koch's postulates, but expand in specific circumstances. One popular model, the Bradford Hill criteria, is an example of broadening the Koch's postulate tenants to not just infectious diseases but also to noninfectious disease causation. Sir Austin Bradford Hill was an English epidemiologist (scientist who studies causation of diseases using mathematical models) who developed his criteria alongside demonstrating the causal link between cigarette smoking and lung cancer in 1965. The Bradford Hill criteria encompass 10 different criteria for the determination of causation: (1) strength of association (effect size), which emphasizes that the larger the association, the more likely the association is true;

(2) reproducibility, meaning that the more experimental data that show a similar effect, the more likely it is true; (3) specificity, where a specific population exposed to a specific disease is more likely to be due to the suspected exposure factor; (4) temporality, where the exposure has to occur before disease development; (5) dose-response relationship, where the more concentrated the exposure factor is, the more severe the disease expression; (6) plausibility, where a mechanism is identified and plausible; (7) coherence, where epidemiological data are corroborated by laboratory results; (8) experiment, which is linked to reproducibility, and shows that the hypothesis of exposure factor results in disease in a specific model; (9) analogy, where there are similarities between an observed association and other known associations; and (10) when the factor is removed from a diseased individual, the disease improves or disappears. The last criterion cannot always be achieved in cases where long-term injury has occurred, but improvement would still be possible with clearing an infection.

Even though Bradford Hill criteria are still used, there are discrepancies with applying these, as well as other variations of Koch's postulates. Opponents to the use of the Bradford Hill criteria state that it cannot be used as exclusive criteria for proving causality, but the use of the criteria is helpful when applied to experimental outcome results. So, it appears that there are no perfect criteria for any given scenario, but a melding of criteria such as Koch's postulates and Bradford Hill criteria, especially during infectious disease outbreaks, is scientific common sense.

Concluding Remarks

In conclusion, the advent of germ theory produced by Louis Pasteur was an essential step to understand the pathological agent, mechanism of disease, and measures that need to be taken to control or prevent disease transmission caused by microbial organisms. As with many aspects of scientific knowledge, the Enlightenment, and application of the scientific method, enabled many early scientists to set foot on the right path to question incorrect and antiquated beliefs. Through logic and skill, and with the help of technological advances, germ theory has been expanded to incorporate the

gaps in understanding based on diseases that don't fit the set of defined criteria of many better understood infectious diseases. As technology continues to advance, and newer infectious diseases emerge, there will be even more demand to redefine causation of disease.

GÖDEL'S INCOMPLETENESS THEOREMS

Gödel's incompleteness theorems belong to the so-called *limitation theorems*. They indicate some inner limitations of the axiomatic method. To this group also belong the Löwenheim-Skolem–Tarski theorem (on the existence of a countable model for any consistent theory), Tarski's theorem (on the undefinability of the concept of truth), and Church's theorem (on the undecidability of the predicate calculus). All of them have far-reaching consequences for logic, for the foundations of mathematics, and for the philosophy of mathematics. They are also important for general philosophy, in particular for epistemology and methodology. However, in the latter case, the consequences depend on various additional factors, for example, on interpretations and on whether the precise assumptions of those theorems are really fulfilled.

Historical Background of Gödel's Theorems

Ever since Plato, Aristotle, and Euclid, the axiomatic method has been considered as the best method of justifying and organizing scientific knowledge. *Elements* of Euclid (4th century B.C.E.) are treated as a pattern of this method. They established a paradigm in mathematics and a pattern of a scientific theory which have been admired and followed. Since Euclid and until the end of the 19th century, mathematics was in principle developed and presented in the form of axiomatic theories (in practice, rather quasi-axiomatic) based—according to methodological principles formulated by Aristotle—axioms, postulates, and definitions. According to this, proof was the basic method of justification in mathematics. Every theorem should be proved; a proof was in fact the sole accepted method for convincing readers of the truth of claimed statements. In research practice, however, the method was not precise enough. In fact, theories have been formulated in imprecise colloquial language, since there were no precisely formulated and defined principles and inference rules. The situation changed with the development of mathematical logic at the turn of the 20th century. This enabled the introduction of formalized axiomatic systems, which provided strict and precise frameworks for constructing

mathematical theories and, in particular, made the concept of a (mathematical) proof precise. Some difficulties, however, appeared to be connected with some limitations of the formalism of logic—indicated just by the limitation theorems.

At the end of the 19th century, the German mathematician Georg Cantor developed a new theory called *set theory*. It provided a useful concept of a set, which—together with the new mathematical logic—enabled the development of mathematics in a more strict and precise way. It also provided the theory of (actual) infinity—an unavoidable mathematical concept. However, Cantor's concept of a set was not precise enough, and soon some paradoxes appeared. Various solutions have since been proposed.

One of the proposals was the reduction of mathematics to logic. This idea forms so-called *logicism*—one of the main trends in the philosophy and methodology of mathematics founded by German philosopher and logician Gottlob Frege (1848–1925) and developed by English philosophers and logicians Bertrand Russell (1872–1970) and Alfred North Whitehead (1861–1947). Another proposed solution was intuitionism, founded by the Dutch mathematician Luitzen Egbertus Jan Brouwer (1881–1966) and developed by his student Arend Heyting (1898–1980). It treats mathematics as an activity of the human mind, based on a primitive intuition of natural numbers and not as a collection of axiomatic theories.

A third proposal was the conception of German mathematician David Hilbert (1862–1943), called *formalism*. It turned out to be most promising one. Hilbert proposed to secure and justify classical mathematics (dealing with the actual infinity) with the help of finite objects which are directly and intuitively given. He proposed to use syntactical means; that is, to refer only to formulas and abstracting (for methodological purposes only!) from their meaning. According to Hilbert, this should be done by considering mathematical theories as formalized theories based on classical logic and by proving that they are consistent and complete. Add that a theory is consistent if no pair of inconsistent sentences like *A* and *not-A* can be proved in it, and it is complete if any problem formulated in the language of the theory can be solved (decided) on the basis of its axioms. In this approach a proof (called: *formal proof*) was

simply (reduced to) a sequence of formulas beginning with axioms, such that each member of it is either an axiom or is obtained from previous members by one of accepted inference rules. Such sequences are in fact finite objects given directly and intuitively, hence they can be investigated by finite, syntactical methods.

Hopes that Hilbert's program could be realized were raised by the Completeness Theorem proved by Kurt Gödel in his doctoral dissertation *Über die Vollständigkeit des Logikkalküls* (1929). It showed that means of the classical logic are in a certain sense sufficient and rich enough, that one can hope that they suffice to reconstruct any proof appearing in real research practice of mathematics as a formal proof.

Those hopes were dispelled, however, by Gödel's incompleteness theorems, proved some months later.

Gödel's First and Second Incompleteness Theorems

In 1930, Gödel proved a theorem called today *Gödel's First Incompleteness Theorem*. It states that

Every consistent theory *T* based on an effectively given set of axioms and containing the arithmetic of natural numbers is essentially incomplete, i.e., it is incomplete and any of its consistent extensions (based on an effectively given set of axioms) is also incomplete.

Add that a theory *T* is incomplete if and only if there are sentences *A* formulated in the language of the theory *T* which cannot be decided by *T*; that is, neither *A* nor *not-A* (symbolically: $\sim A$) can be proved in *T*. Such sentences are called *undecidable* (in *T*).

The theorem was announced for the first time during the Second Conference on Epistemology of Exact Sciences held in Königsberg, East Prussia, September 5–7, 1930. Gödel presented there a 20-minute talk devoted to the results of his doctoral dissertation and a day later he took part in a discussion on the foundations of mathematics and announced his First Incompleteness Theorem. The theorem was published in January 1931 in the paper “Über formal unentscheidbare Sätze der ‘Principia Mathematica’ und verwandter Systeme. I” (*Monatshefte für Mathematik und Physik* 38

(1931), 173–198). Add that in June 1932, this paper was presented by Gödel to the University of Vienna as a *Habilitationsschrift* and on the basis of it he was granted in March 1933 the *venia legendi* and became *Privatdozent*.

At the end of the paper “Über formal unentscheidbare Sätze . . .” Gödel announced also what became known as *Gödel's Second Incompleteness Theorem*. It says that:

No consistent theory T based on an effectively given set of axioms and containing the arithmetic of natural proves its own consistency—in fact the proof of the consistency of T requires means stronger than those of T itself.

Gödel promised to publish the proof of this theorem in the second part of the paper, which would be written soon. In fact the second part was never written and Gödel never published a proof of the Second Incompleteness Theorem. He explained this by saying that in the meantime the result was promptly accepted and hence there was no need to publish it. Add that the hint to the proof given by Gödel in the indicated paper has turned out to be incorrect. The first correct proof was published by D. Hilbert and P. Bernays in the second volume of their monograph *Grundlagen der Mathematik* (1939).

The First Incompleteness Theorem was proved by a sophisticated method. Gödel used the idea of representing formulas of a theory by natural numbers (so-called *arithmetization of syntax*) introduced in fact already by Gottfried Wilhelm Leibniz (1646–1716) as well as the Liar paradox known already by the ancient Greeks. He observed that by replacing truth in this paradox by provability (which in contrast to truth can be defined—via arithmetization—in the language of the theory), one can construct a sentence in the language of the considered theory stating of itself (a so-called *self-reference sentence*) “I am not provable in the theory.” This was just the undecidable sentence (called a *Gödel sentence*) indicating the incompleteness of the theory. The same procedure can be now applied to any consistent extension of the given theory. Hence any such extension is also incomplete and consequently the theory is essentially incomplete.

The method of arithmetization of the language of a theory (of its syntax) enables the translation of

metatheoretical statements (= statements about a theory) into sentences of the language of the theory itself. Hence, a metatheoretical statement “theory T is consistent” can be translated into the language of the theory T . The Second Incompleteness Theorem shows that such a sentence is not provable in T ; more exactly, one proves that this sentence is equivalent (in T) to Gödel's undecidable sentence. However, it has turned out that the way in which the translation is done plays here a crucial role.

Some Technical Details

Among the important tools used in proofs of Gödel's theorems is the concept of effectiveness and of computable function and relation. Consider functions and relations in the set of natural numbers $\mathbb{N}$. Recall that a function f is said to be computable if and only if there exists a mechanical method by which for any arguments $a_1, \dots, a_n$ the value $f(a_1, \dots, a_n)$ can be calculated in a finite number of prescribed steps. Similarly a relations R on $\mathbb{N}$ is said to be computable if and only if there exists a mechanical method such that for any arguments $a_1, \dots, a_n$, it can be decided in a finite number of prescribed steps whether the relations R holds or not. This intuitive notion is made strict and precise by introducing the concepts of a recursive function and relation.

DEFINITION. The set of recursive functions is the smallest set of functions containing the functions $+$ (addition), $\cdot$ (multiplication), $K_<$ (characteristic function of the relations $<$) and projection functions and closed under superposition and the operation of effective minimum.

DEFINITION. A relation R is said to be recursive if and only if its characteristic function K_R is recursive.

Denote by PA the formal arithmetic of natural numbers (called *Peano arithmetic*). It is a first order formal axiomatic theory formulated in the language with the following nonlogical symbols: 0 (zero), S (successor), $+$ (addition), $\cdot$ (multiplication) and based on the following nonlogical axioms:

$$(A1) \quad S(x) = S(y) \rightarrow x = y,$$

$$(A2) \quad \sim(0 = S(x)),$$

$$(A3) \quad x + 0 = x,$$

- (A4) $x + S(y) = S(x + y)$,
 (A5) $x \cdot 0 = 0$,
 (A6) $x \cdot S(y) = x \cdot y + x$,
 (A7) $A(0) \wedge \forall x [A(x) \rightarrow A(S(x))] \rightarrow \forall x A(x)$

where the symbol $\forall$ denotes the universal quantifier “for every . . .”.

The crucial connection between recursive functions and relations on the one side and Peano arithmetic on the other is the concept of representability. Denote by $\mathbf{n}$ (for a natural number n) its name expressed in the language of PA (it is called *numeral*). It is defined in the following way: $\mathbf{n}$ is the term $S(S(\dots S(0)\dots))$ in which the symbol S appears n times.

DEFINITION. A relations R is said to be strongly representable in PA if and only if there exists a formula A of the language of PA such that for any natural numbers $k_1, \dots, k_n$:

$$\begin{aligned} R(k_1, \dots, k_n) &\text{ if and only if } \text{PA} \vdash A(\mathbf{k}_1, \dots, \mathbf{k}_n), \\ \sim R(k_1, \dots, k_n) &\text{ if and only if } \text{PA} \vdash \sim A(\mathbf{k}_1, \dots, \mathbf{k}_n). \end{aligned}$$

where the symbol $\text{PA} \vdash A$ means that A is provable in PA (PA proves A).

In a similar way one defines the concept of representability of a function in PA:

DEFINITION. A function f is representable in PA if and only if there exists a formula A of the language of PA such that for any natural numbers $k_1, \dots, k_n$:

$$\text{PA} \vdash \wedge y [A(\mathbf{k}_1, \dots, \mathbf{k}_n, y) \leftrightarrow (y = f(k_1, \dots, k_n))].$$

THEOREM. Every recursive function is representable in Peano arithmetic PA. Every recursive relation is strongly representable in Peano arithmetic PA.

Another tool used in the proof of Gödel's theorems is arithmetization (sometimes called *gödlization*). It consists of establishing a one-to-one correspondence between expressions of the language of a given theory (in our case PA, though the procedure is general and can be applied to any formal theory) and natural numbers. Using such a correspondence one can translate metamathematical statements about a theory as a formal system into statements about natural numbers. If the

theory is PA (= arithmetic of natural numbers) or its extension, then one can speak about PA in itself! What more, fundamental metamathematical relations such as, for example, being a formula, being a sentence, being a proof of a given formula, and so on, can be translated in this way into certain recursive relations, hence into relations strongly representable in Peano arithmetic. Consequently one can speak about formal system of arithmetic of natural numbers (or other formal theory containing it) and about its properties as a theory in the system itself! This is the essence of Gödel's idea.

We will not describe here the arithmetization in details—it is tedious and complicated (details can be found, for example, in the monograph by R. Murawski, *Recursive Functions and Metamathematics. Problems of Completeness and Decidability*, Gödel's Theorems. Note only that if A is a formula of the language of PA, then the symbol $\underline{A}$ will denote the natural number corresponding to the formula A under the given arithmetization. The number $\underline{A}$ is called the *Gödel number* of A .

Using arithmetization one can define certain recursive relations and functions corresponding to various metamathematical relations and functions concerning PA. In particular, one obtains in this way the relations $\text{Prf}(x, y)$ corresponding to the metamathematical relation of being a proof of a formula. This means that if $\underline{A}$ is the Gödel number of a formula A and n is a natural number then

$\text{Prf}(n, A)$ holds if and only if n is the code of a (finite) sequence of natural numbers being Gödel numbers of formulas forming a (formal) proof of A in PA,

briefly:

$\text{Prf}(n, \underline{A})$ holds if and only if n is the code of a (formal) proof of A in PA,

But the relation Prf is recursive. Hence, it is strongly representable in Peano arithmetic PA. Let Prf denotes any formula of PA strongly representing Prf in PA. Consider now the relations:

$R(x, y) \leftrightarrow x$ is (a Gödel number of) a formula B with one free variable and y is a (Gödel number of) a proof of the formula $B(\underline{b})$.

Let us explain that $B(B)$ means here the formula B in which one substituted for the variable x the numeral corresponding to the Gödel number of the formula B (hence of the formula itself).

It can be shown that the relations R is recursive, hence strongly representable in PA. Using this fact one can construct a sentence (i.e., a formula without free variables) of the language of PA stating its own unprovability. Denote it by A_G and call it a Gödel sentence. Hence, the Gödel sentence says: "I am not a theorem of PA."

Before we formulate Gödel's First Incompleteness Theorem, we need still one notion.

DEFINITION. Peano arithmetic is said to be ω -consistent if and only if for any formula $A(x)$:

if $PA \vdash A(0)$, $PA \vdash A(1)$, $PA \vdash A(2)$, $\dots$ then $PA \not\vdash \exists x \sim A(x)$,

where $\exists$ denotes the existential quantifier, there exists $\dots$.

Hence ω -consistency means that if Peano arithmetic proves that every particular number n has the property A , then PA does not prove that there exists a counterexample for A (which does not mean that PA proves "for every x , $A(x)$ "!).

Note that the concept of ω -consistency is stronger than the concept of consistency, namely if a theory T is ω -consistent then it is consistent but not *vice versa*.

THEOREM (First Incompleteness Theorem; Gödel). If Peano arithmetic PA is ω -consistent, then the Gödel sentence A_G is undecidable in PA, that is, $PA \not\vdash A_G$ and $PA \not\vdash \sim A_G$. Hence, PA is incomplete.

It can be observed that the stronger assumption that PA is ω -consistent is needed only in the proof of $PA \not\vdash \sim A_G$. For the proof of $PA \not\vdash A_G$ the assumption of consistency of PA suffices.

Observe also that the described procedure can be applied to any ω -consistent extension T of PA based on recursive set of axioms (this is needed in order to secure the recursiveness, and hence strong representability, of the relations Prf). In this way, one obtains an extension of Gödel's First Incompleteness Theorem stating that PA is not only incomplete but even essentially incomplete.

It was shown later by Rosser that by considering another self-referential sentence one can eliminate from the First Incompleteness Theorem the

assumption of ω -consistency. The sentence of Rosser (denote it by A_R) says: "if there exists a proof (in PA) of the formula A_R then there exists also a proof (with even a smaller or equal Gödel number) of the formula $\sim A_R$." Hence, it says about itself that if it is a theorem of PA, then its negation can also be proved in PA (and its proof is not longer).

THEOREM (Rosser). If Peano arithmetic PA is consistent, then the Rosser sentence A_R is undecidable in PA, that is, $PA \not\vdash A_R$ and $PA \not\vdash \sim A_R$. Hence PA is incomplete.

Observe that since one of sentences of the pair A_G and $\sim A_G$ (similarly: A_R and $\sim A_R$) is true in the standard model of arithmetic $(\mathbb{N}, 0, S, +, \cdot)$, but none of them is a theorem of PA one obtains that there are true sentences (in this case A_G and A_R) which cannot be proved in PA! A careful analysis of the structure of sentences A_G and A_R shows that both are of the form "there does not exist x such that B " where B contains only propositional connectives and bounded quantifiers, hence of the form "for every x , $\sim B$." Formulas of such a form are called *formulas of the class Π_1* . Negations of such formulas, hence formulas of the form "there exists x such that B " where B contains only propositional connectives and bounded quantifiers are called *formulas of the class Σ_1* . It can be proved that formulas of the class Σ_1 , hence existential formulas are true in the model $(\mathbb{N}, 0, S, +, \cdot)$ if and only if they are provable in PA (are theorems of PA).

To formulate Second Incompleteness Theorem observe that the condition that theory T is consistent is equivalent to the condition: not every formula is a theorem of T (hence: there exists a formula A such that A is not a theorem of T).

Let Prf be a formula of the language of PA strongly representing in PA the recursive relations Prf and let Pr be the formula $\exists x Prf(x, y)$ (it says: there exists x such that x is a proof of y , hence: y is a theorem). Consider the formula Con_{PA} of the form $\sim Pr(0 = 1)$. It says: "the formula $0 = 1$ is not a theorem of PA," hence: "PA is consistent." Since there can exist various formulas Prf strongly representing the relation Prf , so the formula Con_{PA} is not uniquely defined—it depends on the choice of Prf . If the latter (and consequently also Pr) satisfies certain conditions called *derivability conditions*, then Gödel's Second Incompleteness Theorem holds. Derivability conditions require that the formula Prf not only numerically (in the sense of representability) corresponds to

the provability but also formally reflects some basic metamathematical properties of it. Derivability conditions were formulated for the first time by D. Hilbert and P. Bernays in the second volume of their monograph *Grundlagen der Mathematik*.

THEOREM (Second Incompleteness Theorem; Gödel). $PA \text{ non } \vdash \text{Con}_{PA}$.

Observe that the described procedure can be applied to any formal theory based on a recursive set of axioms and containing Peano arithmetic. This means that no such theory proves its own consistency.

Using techniques similar to those applied in proofs of Gödel's incompleteness theorems one can show that:

- (1) The set Thm_{PA} of (Gödel numbers of) theorems of PA and the set neg_{PA} of (Gödel numbers of) negations of theorems of PA cannot be separated by a recursive set, that is, there exists no recursive set X such that $\text{Thm}_{PA} \subseteq X$ and $\text{neg}_{PA} \cap X = \emptyset$.
- (2) The set Thm_{PA} of (Gödel numbers of) theorems of PA is not recursive.

Observe that the contents of Gödel and Rosser undecidable sentences is in fact a bit artificial from the point of view of a research practice of a *normal* mathematician working in number theory or arithmetic of natural numbers. In fact they have a metamathematical and not directly mathematical contents. Therefore, there arose a problem whether there exists examples of undecidable sentences of mathematically (in particular number-theoretically) interesting contents (whatever it could mean). It was solved by J. Paris and L. Harrington, who constructed an example of an undecidable sentence of combinatorial contents (a generalization of Finite Ramsey Theorem) and by Paris and L. Kirby, who provided an example of an undecidable sentence of a purely number-theoretic contents (based on the idea of Goodstein sequence)—for details see the monograph *Recursive Functions* mentioned above.

Reception of Gödel's Incompleteness Theorems

As noted earlier, the First Incompleteness Theorem was announced by Gödel for the first time during the Second Conference on Epistemology of Exact

Sciences held in Königsberg, September 5–7, 1930. It seems that all but a very few conference participants were unaware of the meaning and importance of those results. There was no discussion after Gödel's pronouncement. In the proceedings of the conference, Gödel's name does not appear. At least two persons among those attending the conference should have had foreknowledge of Gödel's result: Hans Hahn, the supervisor of Gödel's doctoral dissertation, and Rudolf Carnap. John von Neumann seems to have been the only participant who grasped the meaning of Gödel's theorem. During the journey home from the conference, he proved a theorem on the unprovability of the consistency of arithmetic in arithmetic itself. In the meantime, Gödel developed his Second Incompleteness Theorem.

Hilbert took part in the conference in Königsberg but did not attend the discussion during which Gödel announced his incompleteness result. He learned about them from P. Bernays only in January 1931 and was at the beginning "somewhat angry" (C. Reid). The irritation and frustration passed in course of time and Hilbert tried to approach the new situation in a more constructive way.

Another leading mathematician of that time, Ernst Zermelo did not accept Gödel's results and turned out to be one of Gödel's strongest critics, claiming that there is a contradiction in the proof by Gödel. In fact, the main obstacle to their understanding each other was that of deep disagreements in their philosophical views on mathematics.

Emil Post's results from 1920–1921 (on the decision problem for formal systems) anticipated results by Gödel on the incompleteness and undecidability of systems of first-order logic. He knew that his results were, as he wrote, "fragmentary." He never published them, and he gave up the research. Only after the publication of Gödel's results did he attempt to publish them, but his paper was rejected. Post always held Gödel's theorems in high esteem and expressed the greatest admiration for them. He never sought to diminish Gödel's achievement as, for example, Paul Finsler from Zurich did. The latter claimed that he had already obtained similar results in 1926. However, a careful inspection of his paper proved that Gödel was actually the first, but Finsler did not give in.

There also appeared some people claiming that Gödel's theorems were incorrect and false, that Gödel had simply discovered a new antinomy.

Such were the opinions of Charles Perelman (paper from 1936), Marcel Barzin (paper from 1940), or Jerzy Kuczyński (paper from 1938). All such opinions were criticized, and the arguments provided by the authors turned out to be wrong.

Interesting is the reaction to Gödel's theorems of two leading philosophers: Bertrand Russell and Ludwig Wittgenstein. It seems that Wittgenstein failed to understand Gödel's results. Russell reacted to Gödel's results in an ambiguous way. It seems that he was of the same opinion as Gödel, namely that by passing to higher types one can obtain formal systems such that the undecidable propositions constructed within each system are decidable in higher systems. In an unpublished letter to Leon Henkin, he admitted that Gödel's work was of fundamental importance and that he was puzzled by it. Gödel wrote in a letter to Robinson: "Russell evidently misinterprets my results; however he does so in a very interesting manner [...]."

Philosophical Implications of Gödel's Incompleteness Theorems

The First Incompleteness Theorem indicates certain limitations of the axiomatic-deductive method. In fact, any consistent formal theory containing arithmetic of natural numbers (and based on an effectively given set of axioms) is essentially incomplete. Hence, the whole of mathematics cannot be reduced to a single axiomatic system. Even more, a single theory cannot incorporate the whole truth about natural numbers. There will always be undecidable sentences of the form $\forall xA(x)$ such that all particular instances of A , that is, sentences of the form $A(0)$, $A(1)$, $A(2)$, . . . are provable. So one cannot construct a consistent and complete system of arithmetic, and all the more so of the whole of mathematics (cf. Hilbert's program described above). Even more, the particular formalization that is used is in fact irrelevant—Gödel's incompleteness results hold for any formalization provided the condition of recursiveness of the set of axioms is satisfied. Add that the incompleteness can be removed by allowing an *infinitary* rule of inference; for example, the ω -rule which leads from infinitely many premises $A(0)$, $A(1)$, $A(2)$, . . . to the conclusion $\forall xA(x)$ (which changes the character of the classical logic) or by admitting methods of set theory (with actual

infinity). Hence, infinite methods are necessary even in investigations of finite objects (such as, e.g., natural numbers).

Gödel's theorems revealed the distinction between provability and validity (truth). Every sentence provable in a theory is true in all its models but not *vice versa*; in other words, there are true (in the intended model) sentences that are not provable. The gap between provability and truth is big: the relation of being a theorem (being provable) can be defined by a Σ_1 formula whereas the concept of truth for formulas of a given theory T is undefinable in the language of T (cf. Tarski's theorem). Hence, the concept of semantical validity (truth) cannot be adequately characterized by syntactic validity (provability). One can say that the concept of truth transcends the concept of a (formal) proof, that syntax is weaker and poorer than semantics.

Another consequence of the First Incompleteness Theorem is that methods applied and admitted in mathematics as well as the creative initiative of mathematicians cannot be *a priori* bounded or limited by formal theories. Formalized theories are not fully adequate with respect to the usual research practice of mathematicians; in particular, the concept of a formal proof is not fully adequate with respect of the concept of proof used in mathematical practice. It is not a strict counterpart of informal proofs provided by mathematicians. The latter are rather argumentations that should convince readers of the correctness and truth of claimed statement; they have rather psychological (and not strictly logical) character. Any correct methods can be used in them (and formal theories limit such methods).

Using the First Incompleteness Theorem and Gödel's Completeness Theorem, one can show that there exist (beside the standard model) a rich variety of different (nonisomorphic) models of PA (the same holds for any extension of it).

The Second Incompleteness Theorem shows that in order to prove the consistency of a theory one needs means stronger than those available in the theory itself. In particular, it is impossible to prove the consistency of classical mathematics (which uses the concept of an actual infinity) by finite methods. This struck a blow to Hilbert's program; however, it did not reject it. In fact Hilbert's program has been developed in two directions: generalized Hilbert's program (the scope of

available methods is extended to, e.g., constructive ones) and relativized Hilbert's program (for which fragments of classical mathematics the original Hilbert's program can be realized).

There exist no absolute consistency proofs—only proofs of the relative consistency (if T_1 is consistent, then T_2 is also consistent) can be provided. Mathematicians can *never* be *sure* that their theories are consistent—one can only *believe* in the consistency of the considered theory (because so far no inconsistency was discovered in it and when in the past an inconsistency has been found in mathematics then it was always possible to eliminate it).

Gödel's theorems are also connected with problems of artificial intelligence. One can ask whether the human mind functions like a machine (computer), and whether the scientific activity of mathematicians can be replaced by a computer. If one assumes that a computer works like a formal axiomatic system (and this assumption is reasonable), then, it might seem, the answer should be *no*. Gödel's theorems showing certain cognitive limits of the axiomatic method indicate also some limits of the abilities of computers. But do they indicate also limitations of the cognitive abilities of human beings? We are able to decide sentences that are undecidable in some given axiomatic theories by admitting appropriate stronger methods (axioms or inference rules). Hence, again it might seem, the answer should be in fact negative.

However computers, sufficiently augmented with new rules, can do the same. Thus it is not clear that there are any questions that humans can answer that are outside the scope of what some computer, and hence some formal system, can decide.

HEALTH CARE SCIENCE

Health care science is an interdisciplinary field of applied sciences that explores how technology, science, communication, mathematics, and engineering shape, affect, and influence health care delivery. Health care science encompasses:

- The use of theory in the sciences and humanities to advance health care so as to improve health outcomes and quality of life for patients and communities;
- Models of health care delivery such as the biomedical and biopsychosocial models, as well as patient-centered communication and culturally competent communication models;
- Social and cultural determinants of health;
- The role of eHealth and technology in improving patient health outcomes and relationships with health care providers;
- Medical and social sciences that health care professionals use to advance health care;
- Scientists working on finding new treatments and cures for a variety of health issues; and
- Health care at local, national, and global levels.

The main goal of health care science research and practice, according to Hilla Brink, Christa Van der Walt, and Gisela Van Rensburg, is to provide strong evidence upon which the improvement of health care delivery can be based.

Models of Health Care Delivery

At the heart of health care science are the different types of health care delivery and how those types have evolved historically. Health can be socially constructed and understood in numerous ways, but two frameworks have been dominant and have typically shaped health care delivery: the *biomedical perspective* and the *biopsychosocial perspective*. The paternalistic and physician-centered biomedical perspective has existed since the mid-19th century and is a derivative of Louis Pasteur's germ theory of disease. Devised by medical scientists to study and cure diseases, it is a scientific model that emphasizes health as the absence of illness. As the historically predominant model of health care delivery, it is a very linear, objective perspective that places power in the hands of the physician; it is very much focused on physical health, the concept of disease, and is interested in illnesses and experiences that are verifiable. The biomedical model has both its advantages and disadvantages. Advantages, for example, include its successes in eliminating infectious diseases in the mid-19th century and dramatically increasing life expectancy in the 20th century. Disadvantages, however, include its reductionist and exclusionary nature. Many critics have noted that the biomedical model of health care delivery is exclusionary because it privileges biological determinants of illness and does not take into consideration illness symptoms; the social, behavioral, and psychological dimensions of illness; and patients' lived experiences of their health and illness.

The paradigm shift to the biopsychosocial model began in 1977 when George Engel, a professor of psychiatry and medicine, argued for a new medical model that views and treats illness not just as scientific issues, but instead as human experiences situated within sociocultural contexts. In Engel's seminal article on the biopsychosocial model, he detailed how the biopsychosocial model allows for five main components that were excluded from the biomedical model:

1. Room for variability in how various illnesses and diseases are clinically expressed and personally expressed (e.g., the clinical definition of cancer and personal definitions of cancer);
2. The ability to understand how to relate biomedical illnesses and diseases to behavioral and psychological expressions of the illness (e.g., taking into consideration both scientific and physiological aspects of an illness, as well as patients' expressions of how the illness or disease affects them);
3. Room for more discussion of when a patient identifies as *sick* and accepts the role of patient, meaning discussion of both the biochemical aspects and psychological/social aspects of disease;
4. An emphasis on treating both the biological and mental well-being of patients; and
5. A focus on improving the patient-provider relationship.

Thus, the biopsychosocial model extends the biomedical model because it adds additional layers to the illness experience and places more of an emphasis on the patient. It also requires health care providers to sharpen their care repertoire by including medical, biological, social, and psychological skill sets to gain a more holistic approach to treating patients. Since it is more subjective and views health more holistically, it focuses on every aspect of the patient's health, that is, the mental, physical, cultural, spiritual, and emotional aspects that together contribute to a person's overall well-being.

Located within these two paradigms of health care delivery are *the voice of medicine* and *the voice of the lifeworld*. Elliot Mishler made sense of the difference between these two perspectives by noting that these two voices often exist, push,

and pull at each other within medical encounters. Although patients and health care providers might be discussing the same illness, disease, and physiological symptoms, what is truly occurring is perhaps a fissure between the *voice of medicine*, the physician's biomedical approach to exploring illness and disease, and the *voice of the lifeworld*, which includes familial influences, peer influences, and other sociocultural understandings of health, disease, and illness. For example, if a health care provider and patient are discussing the patient's diabetes, the physician might discuss the patient's diabetes in terms of A1C levels and a need for more exercise and better diet choices; from within the domain of the lifeworld, the patient may be thinking of diabetes in terms of how it will affect their family members and the ability to complete job tasks at work.

Thus, the biomedical and biopsychosocial paradigms, as well as *the voice of medicine* and the *voice of the lifeworld*, have laid the foundation for a new paradigm of health care delivery that has gained traction in both theoretical and practical circles: patient-centered communication.

Patient-Centered Communication and Culturally Competent Communication Frameworks

Patient-centered care has recently advanced to the forefront of conversations about quality care. Argued to improve patient health outcomes and satisfaction with care, patient-centered care aims to enhance the quality of personal, professional, and organizational relationships. Ronald M. Epstein and Richard L. Street posit that as it advocates for helping patients become more active with their health care by becoming more active and outspoken in the health care encounter, patient-centered care challenges centuries of physician-centered and physician-dominated models of health care. Patient-centered care has three core attributes: the consideration of patients' needs, experiences, and perspectives; the provision of opportunities for patients to interact with physicians and participate in their care; and the enhancement and strengthening of the patient-provider relationship. As part of the patient-centered care initiative, patient-centered communication was developed to improve patient satisfaction, incite

better health outcomes, and overall improve patients' quality of care.

Patient-centered communication, according to Epstein and Street, can be defined in terms of patient-provider interaction processes and outcomes. The four main components of this definition include

1. Understanding patients within their own social and psychological contexts;
2. Taking time to elicit, understand, validate, and follow up on patients' perspectives, which includes their feelings, fears, concerns, questions, and expectations;
3. Reaching a shared understanding of the patients' problems and treatments; and
4. The physician sharing the power in the interaction by allowing the patient to participate and share their preferences for care.

For patient-centered communication to work, however, it must be conceptualized as a method of care that extends past the single health care encounter to enhance the patient's satisfaction with care and overall well-being even after the interaction. Behaviors that the physician can use during the encounter to practice patient-centered communication include maintaining eye contact with the patient; nodding to indicate that they understand the patient's communication; encouraging patient participation via both verbal and nonverbal means; encouraging the patient to share their feelings about their health; providing enough information so that the patient feels confident in their understanding of the health topic at hand; asking the patient about how their family members and work context contribute to their understanding of their health; and offering encouragement and nonverbal support—smiling, nodding, or a small tap on the shoulder.

In addition to the three core components of patient-centered communication, there are six core functions of patient-centered communication that, when utilized, can contribute to better health outcomes for patients who are dealing with a variety of health issues: fostering the patient-provider relationship, exchanging information, managing uncertainty, responding to emotions, making decisions, and enabling patient self-management. Epstein and Street note that these functions

overlap and interact with each other to ultimately increase patient satisfaction and improve health outcomes. All play important roles in the same health care interaction. If, for example, a pregnant patient sees her doctor because she wants more information on the amniocentesis procedure, a potentially life-altering procedure due to its invasive nature and the nature of the test information, the successful existence of and performance of all six patient-centered communication functions could be important for her during the medical encounter.

The first function of patient-centered communication, *fostering the patient-provider relationship*, is characterized by relationships between health care providers, patients, and family members that are trustworthy, mutually understanding, and full of rapport. This function takes the relationship between clinicians and patients beyond an advisor-advisee relationship toward a mutually beneficial and equal partnership where patients and their family members feel that they are welcome to participate in the medical encounter. Participation on behalf of both the physician and patient (as well as their family members, if they are present) has the potential to make the patient-provider relationship a healing relationship that is more than an information exchange based upon diagnoses and treatment plans; rather, in addition to information, there is a connection and an exchange of social support, emotional support, advice, and trust.

The second function of patient-centered communication, *exchanging information*, serves two functions: it helps patients gain more information about the health issue at hand, and it also strengthens the patient-provider relationship because the information can reassure the patient, help the patient make more sense of their illness so that a decision can be made about treatment plans, and even reduce patient uncertainty. Information exchange can occur about a variety of topics, including but not limited to illness and disease prevention, illness and disease diagnosis, and illness and disease treatment.

The third function of patient-centered communication, *responding to emotions*, is characterized by a patient-provider relationship in which the physician listens to patients' emotions about their health, takes them seriously, legitimates their

emotions, and then responds with empathy, support, and reassurance. Given that patients' emotions about their health can differ with intensity and at different stages during a disease or illness, it is important for physicians to respond positively and reassuringly to patients' emotions and offer strategies for emotion management and patient well-being.

The fourth patient-centered communication function, *managing uncertainty*, is closely related to responding to emotions and is characterized by a physician's attempt to help their patients alleviate their uncertainty about an illness or disease. Considering that uncertainty about one's health can have detrimental physical and mental effects such as emotional distress, physicians can be patient-centered by acknowledging their patients' uncertainty, offering more information that could help patients understand their health issue more clearly, and responding with empathy so that patients feel more comfortable managing their uncertainty.

The fifth patient-centered communication function, *making decisions*, is characterized by physicians and patients working together to ensure that a high-quality decision has been made about prevention and/or treatment. Epstein and Street note that a high-quality decision is one that is based on the patient's personal values, as well as their understanding of the rationale for the decision. For example, if a pregnant patient discusses the amniocentesis procedure with her physician and is unsure about whether or not to undergo the procedure, a high-quality decision in this case would be one that does not go against her values about life, bodily autonomy, and disability; moreover, it would be a decision that is based on her understanding of what the amniocentesis procedure tests for, how it operates, and whether or not she wants the amniocentesis test information. Regardless of who makes the decision (the physician, the patient, and/or family members), Epstein and Street posit that it is important that the decision-making process is characterized by both the physician and patient participating in the process, meaning they both share information, values, and feelings about the health issue at hand.

The sixth and final patient-centered communication function, *enabling patient self-management*, occurs when physicians ensure that patients are

able to follow through with their own care after they have left the physician's office or medical consultation room and feel empowered to do so. Epstein and Street note that this function is separate because it combines previous functions (information exchange and decision-making) with enablement, which is patients' perceived ability to follow through with their treatment regimen, search for more health-related information, and seek out their physician if necessary. Overall, health care providers offer support to their patients, encourage them, and provide them with information and reassurance so that they feel empowered to manage their health.

Thus, in combination these six functions—fostering the patient-provider relationship, exchanging information, responding to emotions, managing uncertainty, making decisions, and enabling patient self-management—form the basis of patient-centered communication. Other theories and models, such as culturally competent communication, also work to eliminate misunderstandings within patient-provider encounters and overall improve health care and health outcomes.

Culturally competent communication is a model that works to reduce health disparities, improve communication between health care providers and patients, and ultimately improve health outcomes. Richard L. Street and Cayla R. Teal created a culturally competent communication model that health care providers can use to improve their communication skills and models of care when interacting with patients of a variety of cultural, racial, sexual, ethnic, and demographic backgrounds. Their culturally competent communication model includes four critical components—communication repertoire, situational awareness, adaptability, and knowledge about core cultural issues—as well as five critical communication skills, which comprise a skill set that health care providers can use to engage with patients of different backgrounds. Street and Teal posit that this model was designed to elevate health care provider sensitivity to cultural difference and sharpen and refine health care providers' communication competence.

The first component, *communication repertoire*, consists of communication skills and competencies that the health care provider should have in their *communication toolbox*. A health

care provider's communication repertoire should include competencies about how physicians should obtain information, what sorts of information should be obtained within the medical encounter, and how to negotiate with the patient if cultural beliefs or values impede decision-making.

The second component, *situational and self-awareness*, deals with ensuring that health care providers have the power of perception, or the ability to attend to patients' cues and emotions. This power of perception is twofold, though, as it also entails health care providers having the ability to recognize their own implicit perceptions and biases that may affect how they provide care to their patients. If a health care provider has both situational and self-awareness, they will be able to pick up on conversational and cultural nuances and react in a patient-centered manner.

This leads to the third component of the culturally competent communication model, which is adaptability. If health care providers have adaptability, they should be able to adapt to various patients who have different belief systems. The notion of reflection applies to all components of the culturally competent communication model, but more specifically to the adaptability component because adaptability requires that health care providers can reflect upon their patients' actions and cultural belief systems within the actual encounter. Within this model, health care providers should be adaptable and reflective enough to assess their beliefs and their patients' beliefs within the moment to ensure that the most optimal care is being provided.

The fourth component of the culturally competent communication model is *knowledge about core cultural issues*, which suggests that health care providers should have knowledge about cultural groups and social determinants of health, as well as knowledge of how their own implicit biases and perceptions can influence their care and be counteracted. Teaching core cultural issues also includes a module whereby health care providers are reminded that patients might identify with various cultural groups, yet they are also individuals with individual beliefs and values. Health care providers should approach their patients as individuals first and then assess the salience of the patients' cultural beliefs and values. For example, instead of assuming that a patient will reject a

certain procedure or treatment regimen because they are a members of a particular religious group, a physician should approach the patient and then assess how salient the patient's religious beliefs are and how much their religious beliefs will influence their health decisions. This could help avoid any stereotyping and potential embarrassment and hostile feelings in the long run.

Thus, the culturally competent communication model takes patient-centered communication models one step further by incorporating knowledge about core cultural issues as a core component of improving patient-provider relationships and achieving better health outcomes. In addition to the importance of culture, two other demographic categories that have gained traction within health care sciences are race and gender.

Health Disparities and Minority Health

In addition to focusing on different models of health care delivery and different ways to improve health outcomes, another component of health care science includes the study of minority population health, more specifically from race and gender perspectives, and how to reduce and eliminate health disparities that various minorities typically suffer from. As Thomas LaVeist notes, the study of minority health is an important component of health care science because of the dramatic increase of minority races and ethnicities in the United States over the last few decades, particularly Latino and Asian populations. Moreover, Thomas LaVeist notes that current projections indicate that, in combination, minorities in the United States will become the majority population by 2050. Thus, it is imperative that health care professionals dedicate more time and effort to explore and systematically study and understand minority health because *minority health* will soon constitute the greater share of nation's population within the next few decades.

Another reason that the study of minority health has gained traction over the last few decades is because of the increase of health disparities in the United States. LaVeist posits that in general, the distribution of ill health in the United States is set up in such a manner that racial/ethnic minorities have worse health than Whites in most contexts and with a variety of health issues. There

are considerable differences in the incidence, prevalence, morbidity, and mortality for racial/ethnic minorities in the United States as compared with the White population. National data suggest that there are persistent mortality rate disparities for racial/ethnic minorities as compared to Whites, considering that Whites have a lower mortality rate than Native Americans, Hispanic/Latinos, and African Americans. Moreover, although infant mortality rates are steadily declining in the United States, there is still a considerable gap between infant mortality rates for Whites and for racial/ethnic minorities. Thus, health care disparities exist for racial/ethnic minorities regarding a variety of health care issues due to the differences in the access, use, quality of health care, and outcomes of health care services that minorities receive. LaVeist specifies that health care disparities are *racial/ethnic* differences in the quality of health care that are rooted within injustice within the health care system, whereas health care dissimilarities are racial/ethnic differences in health care that are not caused by inequities and injustices.

A myriad of theories can be used to understand and explain health disparities and can be grouped within three categories: socioenvironmental, psychosocial or behavioral, and biophysiological. *Socioenvironmental theories* such as risk of exposure theory, resource deprivation theory, and racial/ethnic segregation theory postulate that health disparities exist because of racial/ethnic differences in the communities in which people live. Different community factors that could influence a person's health include environmental issues such as toxins or pollution, crime, and lack of access to health care and healthy food, to name a few. For example, if an African American or Latino person lives within a rural neighborhood, they might not have access to a grocery store that serves fresh, healthy food or access to a health care clinic. These factors could serve as serious detriments to their care. The second category, the *psychosocial or behavioral category*, includes the weathering hypothesis, John Henryism, and immigration and acculturation theories; LaVeist notes that these theories are related to the aspects of a person's culture that influence their health behaviors. In terms of immigration and acculturation theories, for example, many patients who emigrate

from other countries might be reluctant to accept Westernized views of medicine and Westernized medical practices at the expense of their culturally related health beliefs or practices. In certain cases, this could lead to a clash of disparate cultural views of medicine and result in adverse or negative health outcomes. For example, if a pregnant woman emigrates to the United States from a rural area in Mexico and her American physician recommends she undergo a battery of prenatal screenings and testing, she might be reluctant to accept the tests because perhaps they are not available or highly encouraged in her hometown, they might go against her cultural or religious beliefs, or she might not completely understand how the tests operate and what they test for. The third category, *biophysiological theories*, includes theories such as the slavery hypertension hypothesis and consists of theories that explain how and why there might be certain genetic and biological differences that affect certain racial/ethnic groups.

Thus, health care disparities for racial/ethnic minorities in the United States exist across a wide range of illnesses and diseases and are caused by factors such as low socioeconomic status, lack of access to adequate health care, low health literacy, and racial/ethnic injustices, to name a few. Another arena in which health care disparities exist is women's health, which has also gained traction in health care science research.

Women's Health Care

Along with the study of minority health and health disparities, women's health care has also recently moved to the forefront of health care science. Health care scholars took notice of the health disparities that occurred between men and women and created the women's health care subfield, which focuses specifically on health promotion, mental and emotional wellness, sexual and relational wellness, and chronic illnesses and diseases. Given the reality that men and women's bodies are indeed different, and grounded in the belief that women deserve health care that focuses on their bodies, the women's health care subfield educates women and empowers them to learn about their bodies and also make women's health care a priority at local, national, and international levels. Moreover, women's health care is rooted in

feminist ideals of equality and justice for all women. For example, Cheryl Kolander, Danny Ramsey Ballard, and Cynthia Kay Chandler note that women's health in a global society should become a global priority because, across the globe, women share similar health concerns such as poverty, discrimination, violence, limited access to health-related information, lack of reproductive rights, limited child care services, women-specific disorders and diseases, and gynecological health issues. Thus, the women's health care subfield works to eliminate sexism, misogyny, and injustice in women's health and seeks to improve health care outcomes for all women.

In addition to being rooted within feminist ideals, the women's health care subfield is also rooted within second-wave feminism's women's health movement in the United States. Before the 1960s, women had limited influence in the women's health arena. Angry about the inferior health care that they were receiving and disillusioned with the status of women, women's oppression, and the construction of women's bodies within the health care arena, women collaborated and created the women's health movement. Created at the same time as the civil rights movement, the women's health movement, comprised of feminist and women's health scholars, sought to create equal rights for women within the health care arena. In 1969, 12 women met during a women's liberation conference in Boston and engaged in feminist consciousness raising about their dissatisfaction with their health care physicians. Deciding to pool together their knowledge, The Boston Women's Health Collective was formed and created the landmark text *Our Bodies, Ourselves* in 1970. This text contained information about women's health issues and is still available today. Many feminist scholars and women's health scholars consider this text to signify the beginning of the women's health movement. In addition to exploring women's health from feminist perspectives, the women's health care subfield also explores women's health from a gender disparities perspective. Cheryl Kolander and colleagues note that poverty not only disproportionately affects racial and ethnic minorities but also disproportionally affects women. Moreover, women in the United States are also more likely to report suffering from serious mental illness and other health issues.

Additionally, women's health care research has moved to the forefront of health care science because of the ethnic, class, and gender bias in health research. Historically, a majority of scientific research studies in health care science examined White, middle-class men's health and then extrapolated that data and applied it to women's bodies and racial/ethnic minorities' bodies. This approach has obvious shortcomings, namely that it excluded women and racial/ethnic minorities from important research and could have potentially led to negative health outcomes. This gender and ethnic bias ignored the ways in which gender and ethnicity contribute to health issues and health outcomes and also tried to apply White, middle-class men's health findings to other demographic populations. Thus, the women's health care subfield seeks to understand the unique health care issues that women face and improve health care access and outcomes for women.

Conclusion

Health care science is an interdisciplinary and transdisciplinary field that uses medical science and social science approaches to explore health care delivery and improve health care outcomes. By embracing studies and perspectives from technology, communication, mathematics, and engineering, health care science explores topics such as models of health care interaction, patient-centered communication and culturally competent communication, racial/ethnic health disparities, women's health, and class, gender, and race disparities within health care.

HYPOTHESIS TESTING

Hypothesis testing constitutes a quantitative method for refuting or supporting theories based on observations from a sample. This entry provides an overview of a commonly used statistical procedure that combines Ronald Fisher's statistical theory with Jerzy Neyman and Karl Pearson's approach to drawing inferences from a sample to the population. Historically, these two competing statistical theories produced heated debates between their originators. Later, however, ideas from the two approaches were merged in the social sciences and are often treated as complementary ways for making inferences about the probability of the existence of the hypothesized relationship in the population of interest.

Hypothesis testing in social sciences typically involves testing a hypothesis of relationship between variables (H_1) against a hypothesis of no relationship (H_0). For example, H_1 will suggest that watching educational television programming is associated with better school readiness skills in 4-year-old children, whereas H_0 will maintain that

there is no association between watching educational television programming and school readiness. Statistical tests enable researchers to reject the null hypothesis and conclude that the relationship between the variables observed in the sample was unlikely to occur by chance. This can be interpreted as evidence in support of the theory about the relationship between variables on the population level. However, hypothesis testing cannot definitively confirm or refute the theory. Inferences from test statistics are probabilistic; therefore, they are open to a certain (known) probability of error. The study might fail to detect a relationship between variables that exists in the population (e.g., in the example above—researchers conclude that educational television viewing and school readiness skills are not associated, when in fact they are). Alternatively, a relationship that *does not* exist in the population can be found in the sample, leading to the erroneous conclusion that the variables are related in the population (e.g., researchers conclude that educational television viewing and school readiness skills are positively associated, when, in fact, they are not).

Despite the widespread use of null hypothesis testing, there is an ongoing controversy concerning the validity of this approach. A number of alternatives to null hypothesis testing, such as Bayesian statistics, have been advanced. Within the frequentist statistical approach, reporting confidence intervals and effect sizes to supplement or replace hypothesis testing became a norm in many research fields.

The Logic of Hypothesis Testing

Statistical hypothesis testing rests on the principle of logic called *modus tollens* (from Latin: “the way that denies by denying”). Instead of directly examining the probability of the existence of the hypothesized relationship, this statistical approach aims to show that the opposite (lack of a relationship) is unlikely, and therefore, the hypothesized (i.e., the existence of a relationship) is highly probable. In other words, the statistical test looks at the probability of data (D) to occur in the population in which a no-relationship hypothesis (H_0) is true, $P(D|H_0)$. While researchers, from a theoretical standpoint, are typically interested in demonstrating a relationship between constructs, evidence

in support of this hypothesis is established by showing that the opposite scenario (lack of relationship) is unlikely.

Stating the Hypotheses

The first step in hypothesis testing involves stating the null (H_0) and the alternative (H_1) hypotheses. The alternative hypothesis is the theory driven hypothesis that the researchers hope their data will support. For instance:

H_0 : There will be no difference between the GRE scores of students who took a GRE preparation course and those who did not take it.

H_1 : Students who have completed a GRE preparation course will score higher on a GRE test, compared with students who did not take the course.

In this example, the null hypothesis is a nil hypothesis, as it literally states that there is zero relationship between the variables of interest (here—taking a preparation course and test scores). Researchers almost uniformly use nil null hypotheses, and most statistical packages only allow testing such hypotheses. It is, however, possible to state non-nil null hypotheses, where the null hypothesis allows for a theoretically negligible difference to exist. In the example above, such a set of hypotheses can, for instance, read:

H_0 : Students who have completed a GRE preparation course will score *no more than 10* points above students who did not take the GRE preparation course.

The alternative hypothesis will therefore state:

H_1 : Students who have completed a GRE preparation course will score *10 or more* points above students who did not take the GRE preparation course.

Some researchers argue that non-nil hypotheses are preferable to the pervasive nil null hypotheses. First, non-nil hypotheses are more accurate and realistic. Two means will essentially always be at least somewhat different, and two variables rarely will have a precisely zero correlation. Thus, in actuality, a nil null hypothesis is always false. The question should be whether there is a theoretically or practically meaningful difference between the

means rather than whether the means are different at all. A non-nil hypothesis forces researchers to incorporate practical and theoretical significance considerations in hypothesis testing. In the example above, researchers should ask themselves what constitutes a meaningful effect of a GRE preparation course. What should be the minimal consequential difference in GRE test scores between those who have completed a preparation course and those who did not take the course? For instance, does a mean difference of one point in GRE scores make the cause worthwhile? Instead of rejecting the null hypothesis due to any difference, no matter how trivial it is, theory and prior research findings can be used to inform a non-nil null hypothesis, specifying the minimal effect that has to be observed in the sample. Yet, despite the theoretical advantages of this approach, nil null hypotheses are conventionally used.

Parametric and Nonparametric Test Statistics

Hypothesis testing is based on various test statistics that compare the actual data obtained from the sample and expected distributions. Most commonly in social sciences, researchers use parametric tests that depend on assumptions about the variables' distribution in the population. These typically include assumptions of independence of observations, normality, and homoscedasticity. Violation of these assumptions might bias the estimates yielded by parametric statistics. It may be possible to reduce skewness in asymmetrically distributed data using log, square-root, and other transformations. Yet, in this process, data units lose their original meaning and therefore make the interpretation less intuitive. One evident example is a regression analysis where results based on analysis of raw data can be interpreted as increase in one unit of the independent variable leading to an increase in a certain number of units in the dependent variable. For example, based on the regression results it can be said that every hour of preparation for the test increases the score by 0.86 points. Results of a binomial regression can be interpreted to indicate that every cigarette smoked a day increases one's odds of failing the fitness challenge by 0.08. However, if the independent variables were transformed, it is no longer

possible to express the relationship between the variables in these terms. If the data were log-transformed, then the relationship between the independent and the dependent variable becomes exponential. Rather than each smoked cigarette or each hour of preparation contributing equally to the outcome, the dependent variable grows at a different rate for each unit (the first hour of preparation or the first cigarette has little effect on the exam score or the chances to pass the fitness challenge, but the 10th hour/cigarette makes a substantial contribution to the outcome).

Although the results can be interpreted as average effects of the independent variable on the outcome, from a purely theoretical standpoint transformation makes the test less appropriate for the theory, if the theory originally predicted a linear relationship between variables. In other words, while data transformation assists in meeting the analysis requirements, it also somewhat changes the hypothesis being tested.

Instead of transforming nonnormally distributed data, researchers may consider tests that are more robust to violations of assumptions. Nonparametric tests that do not rely on assumptions concerning the distribution of the examined variables include, among many others, Kruskal–Wallis analysis of variance, Mann–Whitney U (as an alternative to t -test), and nonparametric regression.

The p Value

Test statistics produce p values that indicate the statistical significance of the research result. The p value constitutes the probability to obtain the study result (or a more extreme effect) given that H_0 is true for the population from which the study sample was drawn. The smaller the p value, the more unlikely the result is attributed to chance. In other words, a smaller p value implies a higher probability that the H_0 is false. An arbitrary cut-off point of $p = 0.05$ is commonly used, such that a test statistic with an associated p value larger than that threshold is deemed a statistically non-significant result.

In view of common misinterpretations of test statistics, it is important to underscore what a p value *is not*. First, the p value *cannot* be interpreted as the probability of H_0 being correct. The

test statistic only tells researchers how likely a particular sample-based finding is given that H_0 was true in the population. In other words, it provides information regarding the likelihood of the data obtained, not the hypothesis itself.

Second, p values are sometimes confused with the magnitude of effects. Significance levels, as indicated by p values, are concerned with the probability that the effect observed in a sample is likely to occur in the population. However, the size of the p value says nothing about the size of that effect. A significance level of 0.034 does *not* indicate a more substantial research result or a stronger effect than a $p = 0.043$. As will be discussed below, p values depend to a large extent on sample size. Therefore, if a few more study participants are added to the sample without changing the means and standard deviations of the compared groups, then the same effect size will have different levels of significance. Moreover, owing to differences in sample size, a larger effect size might have smaller p value than a smaller effect. Finally, statistical significance is unrelated to social or clinical significance and the practical implications of the study results. Theory and knowledge of the subject are needed to judge the applied meaningfulness of the findings.

One-Tail Versus Two-Tail Test

A one-tail test is conceptually appropriate when researchers have a strong theoretical reason to hypothesize an effect (e.g., mean difference) in a specific direction, expecting the mean to be either greater or smaller than a certain value. If researchers hypothesize that students who took the preparation course score higher on the GRE test than those who did not take the course, H_1 can be: $\mu_{\text{with course}} - \mu_{\text{no course}} > 0$ and H_0 will read: $\mu_{\text{with course}} - \mu_{\text{no course}} \leq 0$ (those who took the course had the same scores or lower scores than those who did not take the course). The term *one-tail test* stems from the fact that test results that fall in only one of the tails of the distribution (in the example above, positive, right-hand tail) will lead to rejection of the null hypothesis.

A more rigorous test will consider differences in both directions, not just one. To reject the null hypothesis, a more extreme test statistic value is required. The hypothesized relationship is stated

as: $\mu_{\text{with course}} - \mu_{\text{no course}} \neq 0$ and the null hypothesis will include both $\mu_{\text{with course}} - \mu_{\text{no course}} < 0$ and $\mu_{\text{with course}} - \mu_{\text{no course}} > 0$. In this situation, the observation should fall within either the positive or the negative side of the distribution in order to lead to rejection of the H_0 of no difference. Figure 1 presents the differences in the critical regions for one-tailed and two-tailed hypotheses on a sample of distributions of means. The boundaries for a two-tailed test at $\alpha = 5\%$ (eliminating the extreme 2.5% on each side) are $z = 1.96$ and $z = -1.96$. For a one-tail test, the critical value for rejecting

the null hypothesis marks the boundary of the extreme 5% on one of the sides of the distribution at $z = 1.64$ or $z = -1.64$.

One-tail tests have greater statistical power than two-tail tests, giving researchers a better chance to detect effects in the population. However, it is generally less acceptable to use one-tail tests because researchers might miss an effect in the opposite direction. This, in turn, might have serious ethical and practical implications (e.g., when testing the effectiveness of a new drug). The more conservative two-tail test is recommended in many research

Figure 1 Areas of Rejection of H_0 in Two-Tail and One-Tail Test When $p = 0.05$.

fields even when researchers propose theory-driven, directional hypotheses. In other fields, it can be permissible to use a theory-driven one-tailed test that was proposed in advance, before the data have been collected (i.e., never after a two-tailed test yielded a nonsignificant result).

Limitations of Drawing Conclusions From Test Statistics

The probabilistic nature of hypothesis testing limits the scope of inferences that can be made on the basis of this method. Rejection of the null hypothesis does not indicate that the null hypothesis is false (the p value can never be 100%). It only implies that the null hypothesis is highly unlikely to be true. It is similarly impossible to prove the null. Failure to reject H_0 is not equivalent to accepting the null. Rather, the conclusion is that there is merely insufficient evidence for rejecting the null. In fact, hypothesis testing provides little information about the state of the null hypothesis. Hypothesis tests inform about the probability of data occurring in a population, given that H_0 is true ($P(D|H_0)$), but they do not allow one to conclude the inverse probability—the likelihood of H_0 being true, given the data observed ($P(H_0|D)$).

Bayesian statistics provide an alternative approach favored by many critics of traditional methods of hypothesis testing, because this method assesses the probability of each hypothesis more directly. Moreover, the Bayesian hypothesis testing approach considers both the observed data and its prior probability in order to determine the likelihood that the researcher's hypothesis is true, given the evidence.

Errors in Hypothesis Testing

The goal of hypothesis testing is to use data drawn from a sample to learn about the population from which the sample was obtained. However, the process of making inferences from the sample to the population is open to a number of errors. Table 1 presents the definitions of two errors that are most commonly discussed in the literature.

Since not all random samples drawn from a given population represent the population equally well, on rare occasions researchers might base their

statistical conclusions on an extreme sample where they find a significant association between variables otherwise not correlated in the population. Consequently, researchers make a *Type I error*: erroneously rejecting the null hypothesis. In other words, Type I error occurs when the hypothesized relationship was found in the sample and researchers concluded that this is true for the population, when, in fact, the relationship does not exist in the population. The probability of avoiding Type I error (α) is set in advance as a function of the p value. With the threshold for acceptable significance level set at the conventional 0.05, α is 95%. Researchers are therefore taking the risk of wrongly rejecting H_0 in an average of 5% of the tests.

The risk of Type I error increases with the number of tests conducted on the data. Since, for each significant test, there is a probability of 5% that the result was achieved by chance, repeated testing increases the probability that one or more of these tests will be significant. For instance, consider a study in which researchers examine the effectiveness of a new antidepressant medication compared with a placebo. The researchers use repeated measures of five dependent variables. The outcome variables include (1) self-report of the patient's mood, (2) a survey of a patient's family member about the patient's mood, (3) a reaction time test assessing the patient's mood, and two physiological markers of depression: (4) heart rate variability, and (5) prefrontal EEG asymmetry. These five measures are repeated four times: 2, 4, 6, and 8 weeks after the beginning of the treatment. This design produces a total of 20 posttest comparisons between the treatment and the placebo groups. With the p value set at 0.05, there is a 5% chance for researchers to obtain a significant test result by chance alone, which means that, on average, 1 in 20 comparisons between the groups will incorrectly yield a significant outcome. In the example above, suppose that the researchers do not obtain any significant effects of the drug on any outcome except one. They only detect a significant effect of the medication on self-reported mood at the 8-week follow-up. The researchers then conclude that the medication has a long-term effect on mood. However, with so many tests it is conceivable that the significant effect was a fluke rather than valid evidence of the true effect in the population, and the researchers'

conclusion is subject to Type I error. To maintain statistical rigor, various statistical procedures such as that of Bonferroni, of Scheffe, or of Tukey can be used to adjust the results to account for the inflation of α in multiple subtests. These adjustments reduce the so-called *experiment-wise error rate* by decreasing the required p value for each individual test.

The flip side of Type I error is Type II error. *Type II error* occurs when researchers retain H_0 when it is incorrect and falsely conclude that the relationship does not exist in the population. That is to say, whereas Type I error refers to false positives, Type II error involves false negatives. The probability of making Type II error is denoted by β , and $1 - \beta$ (i.e., the probability of not making a Type I error) is termed *statistical power*. As a rule of thumb, researchers feel comfortable with statistical power of 80% (i.e., $\beta = 0.20$).

Three factors play a role in determining statistical power: the probability of a Type I error, effect size, and sample size. First, it is important to note that there is a trade-off between Type I and Type II errors. Reducing power from 80% to 60% (i.e., setting β at 0.40 rather than 0.20) increases the probability of Type II error but makes Type I error less likely. The reverse is also true: the more liberal the researchers are in rejecting the null (e.g., use a p value of 0.10 instead of 0.05), the more likely they are to make a Type I error. However, they will also be less likely to perform Type II error and miss an existing effect. Since α is typically set at the conventional 0.05 or 0.010 level, practically speaking, researchers can improve their power only by adjusting the other two parameters (sample size and effect size).

The second factor is effect size. The larger the effect size (e.g., stronger correlation between variables, or larger mean difference and more homogeneous variances), the more likely one is to observe this effect in the sample. Third, it is easier to detect a significant effect in a larger sample. Even small effect sizes (i.e., minute correlations or tiny mean differences) are more likely to be statistically significant in a very large sample. Even very small correlations such as $r = 0.02$ will yield a very small p value when sample size is in tens of thousands.

The probability of making Type I and Type II errors for each given study is established by researchers based on cost-benefit considerations.

Customarily, however, Type I errors (assuming an effect exists when it does not) are considered to be more serious than Type II errors (missing an existing effect). Thus, by convention, the Type II error rate is set to be four times as large as a Type I error (i.e., 20% vs. 5%, respectively). Depending on the severity of the consequences of making a Type I error, researchers may choose to adhere to a more conservative threshold for rejecting the null. For example, repercussions of Type I error in the case of approving a new drug can be quite dire. Patients might suffer from side effects from an ineffective medication without receiving any of the promised benefits. Moreover, conceivably, more effective treatment will be withheld from these patients. Thus, in medical research, researchers may want to reduce Type I error by increasing α to 0.01 or 0.001 and thereby require stronger evidence to reject the null. This will come at a cost of increasing the chance of making a Type II error. However, the researchers might reason that if the drug is very powerful and produces a substantial effect size, they will have good statistical power to detect this effect, even with a smaller α . It is often better to overlook a small effect size (i.e., minimal advantages of a new medication) and to continue using the old, slightly less effective drug, than to adopt a potentially ineffective treatment, given the lack of long term, follow-up data.

Finally, a less commonly discussed type of incorrect inference is *Type III error* (γ), wherein the researchers correctly reject the null hypothesis but make an error concerning the direction of the effect. A small number of samples can produce an extreme statistic that displays the opposite trend of the effects compared to the population. For example, in the population, most students benefit from taking a GRE preparation course. However, in a very small number of samples from this population, the opposite will be true, and course-takers will score significantly lower than those who did not take the course. The test statistic warrants rejection of the null hypothesis (which is true, because there is, indeed, a difference between course takers and nontakers in the populations), but the researchers draw a wrong conclusion about the direction of the effect in the population (believing that the course reduces GRE scores rather than increases them). Accordingly, the probability of correctly rejecting H_0 equals $1 - \beta - \gamma$.

Table 1 Definitions of Type I and Type II Errors

	<i>Made a Correct Decision</i>	<i>Made an Incorrect Decision</i>
Researchers rejected H_0 based on a significant test result	$1 - \alpha$ (usually is 0.95) Researchers made a correct inference that there <i>is</i> a relationship in the population.	Type I error α (usually set at 0.05) False positive: There is no relationship between the variables in the population, but the researchers concluded that there is a relationship.
Researchers retained H_0 based on a nonsignificant test result	$1 - \beta$ (statistical power, usually 0.80) Researchers made a correct inference that there is <i>no</i> relationship in the population.	Type II error β (usually set at 0.20) False negative: There is a relationship between the variables in the population, but the researchers concluded that there is no relationship.

Type III error is typically attributed to outliers. Thus, not surprisingly, Monte Carlo simulations of Student t -tests reveal that the rate of Type III error is greater in studies using small samples and when comparing groups with discrepant sample sizes.

Alternatives to Hypothesis Testing and Additional Considerations

Despite an ongoing controversy concerning its effectiveness, null hypothesis testing dominates in many social scientific fields such as social psychology, education, and communication studies, and it is prevalent in other sciences such as public health and medicine. Opponents of null hypothesis testing advocate for a number of alternative or supplemental approaches. First, as noted briefly above, Bayesian statistics provides an alternative to traditional hypothesis testing that examines the probability of the theory-driven hypothesis more directly rather than through denial of the opposite. The Bayesian approach to hypothesis testing is also less sensitive to sample size; it does not depend on whether the test is planned or post hoc; and it accounts for the base rate of the phenomenon under examination. Recently, a number of statistical packages began to offer at least some support for this approach, and custom programs can supplement mainstream statistical software.

Second, within the realm of frequentist statistics, confidence intervals allow researchers to estimate the effect in the population, rather than to

test hypotheses. Whereas p values prompt dichotomous decisions about rejection or retention of H_0 , confidence intervals present a range within which the true population effect size is likely to occur with a certain probability (typically, 95%). Larger sample size narrows the interval, thereby increasing the precision of the estimate. If the interval includes the value zero, it is not statistically significant. Thus, proponents of this method maintain that confidence intervals provide the same information as p values with the additional benefit of specifying the upper and lower limits within which lies the true population effect.

Finally, some argue that the practice of hypothesis testing requires that researchers devote too much attention to the question of statistical significance rather than focusing upon effect sizes. In this view, not only does null hypothesis testing depend on an arbitrary cut-off point ($p = 0.05$), but statistical significance is too heavily dependent on sample size. A study conducted on a sample of 40 individuals can yield a nonsignificant correlation ($p = 0.055$), which is likely to be deemed nonpublishable. However, had one collected data from another dozen of research subjects without changing the correlation, the results would now cross the significance threshold (say, down to $p = 0.044$), turning the exact same finding to be statistically significant and, therefore, worthy of a publication. Furthermore, even minute and socially or practically insignificant differences become statistically significant in large enough samples (due to the

relationship between power and sample size). Taken together, tests for significance alone do not provide meaningful information about the theorized relationship between variables.

Recognizing the limitations of null hypothesis testing, many journal editors require supplementing these tests with information about effect size. In many scientific journals, it may no longer be acceptable to simply present a *t*-test indicating that there is a significant difference between two means. Rather, researchers are required to compute Cohen's *d*, eta-squared or some equivalent statistic that addresses the magnitude of the effect. Moreover, given that some researchers do not think of statistical significance as a binary decision, the 6th edition of the American Psychological Association's publication manual urges authors to indicate exact *p* values to two or three decimal places in lieu of *p* value range (for instance, $p = 0.044$ and not $p < 0.05$). In some scientific journals and certain areas of research (e.g., applied behavior analysis), null hypothesis testing is rarely used. Instead, graphic representation of the data and detailed descriptive statistics are used to communicate the research results.

HYPOTHETICO-DEDUCTIVISM

Hypothetico-deductivism involves the testing of theories using observations. From a general statement or theory, a hypothesis is derived, which is then tested using observations. If the observations do not support the hypothesis, the hypothesis is rejected, and subsequently the theory is rejected. If the observations support the hypothesis, the theory is corroborated because testing of the hypothesis is seen as testing of the theory itself.

This is often explained as follows. Suppose we have a theory, *H*, and it predicts the phenomenon *O*. Through our observations, we observe the phenomenon *O* occurring. This does not prove or confirm, however, that *H* is true, because *O* can occur for reasons other than *H*. If *O* is not observed, however, we can reject the theory, *H*. Therefore, a theory can be refuted by a negative observation but cannot be proved by a positive observation. When theories are not refuted, they are merely corroborated and never proven to be true. This can be illustrated using a classic example. If we have a theory that all humans are mortal, we can refute this theory by showing through our observations at least one human who is immortal. If from our observations so far, all humans are mortal, then we have corroborated the theory.

Deduction is an integral part of hypothetico-deductivism. Deduction is a process whereby we derive particular statements from general statements. Deduction can be traced back to Euclidean geometry and Aristotelian logic. Hypothetico-deductivism was first introduced by the British scientist, philosopher, and historian of science William Whewell (1794–1866). Later, Karl Popper (1902–1994), an Austrian-British philosopher, also offered this as an alternative to the inductive methodology.

Hypothetico-deductivism is associated with Popper's falsificationism. In falsification, a statement is classified as false based on observations. He also emphasized that for a theory to be

considered science, it has to be falsifiable. Falsificationism follows a cautious realist ontology and was proposed as a way to deal with the problems of empiricism. As a deductivist, Popper maintains that we reason deductively. He put forward this logic to deal with the problems of induction. According to Popper, induction, which is based on experiences and finite observations, cannot provide a reliable theory. This is because inductive logic will never be able to provide a theory with certainty. Since induction is thus flawed, he proposed a different logic to develop theories.

Popper distinguishes between two categories of philosophers: verificationists and falsificationists. He himself obviously falls in the second category. According to falsificationists, scientific knowledge cannot be definitively proven or established with certainty but remains tentative forever. Rather than using observations to develop a theory (as in induction), falsificationism depends on observations to test theories or to falsify theories. This is an important aspect of hypothetico-deductivism. Popper sees science as a pursuit of truth about the universe, but theories can never be proven or confirmed. Popper rejected the notion of confirmation because it implies verification. According to this view, no amount of evidence can prove a theory to be true, but one instance of contrary evidence will prove that a theory is false. This point can be illustrated using a classic example. Even though we may observe many white swans, this does not prove that all swans are white or will be white; but an observation of a single black swan will immediately prove that our generalization (that all swans are white) is false.

Popper's method starts with a tentative idea, a hypothesis or a set of hypotheses that form a theory. Based on this initial idea, a set of conclusions is made and scrutinized to ensure that it helps the advancement of knowledge regarding the phenomenon being studied. In addition to this, the logic used to deduce these conclusions is also scrutinized. After that, these conclusions are tested by making observations. If the observations are not consistent with our conclusion, it shows that our *theory* is false and must be rejected. If the theory, so called, passes our test—that is, if the observations are consistent with the theory—then the theory is *corroborated* (but *not* thereby proven to be true).

Popper set forth a few requirements for his method. First, theories are considered scientific only if it is possible to falsify them; otherwise they are not considered scientific. In order to be falsified, a theory needs to make a definite claim about the world. The more clearly a theory is stated, the more falsifiable it is. This criterion is important because it differentiates scientific theories from other forms of explanation. Second, theories should always be open to criticisms and the ultimate criticism is the attempt to refute a theory. Theories which are not open to criticism are not considered scientific. Third, if a theory is refuted, it can be modified or substituted by other theories, which will be tested further. Any theory that survives refutation is only corroborated, pending further attempts to falsify the theory. Hence, theories are only accepted provisionally for as long as these theories survive refutation.

Critiques of Hypothetico-Deductivism

Even though hypothetico-deductivism is prevalent among scientists and social scientists as well, it has been criticized by some philosophers for entailing many technical issues. One of the most important criticisms of hypothetico-deductivism is that it does not discuss the source of the propositions in a deductive theory. Popper himself did not discuss this; he was skeptical of any logic of discovery and felt that the context of discovery was psychological. He maintained that the initial discovery phase does not require a logical analysis but that logical analysis is important in the theory-testing stage. He believed that every discovery involves some form of creative intuition or perhaps simply a guess.

Popper's view that there is no logic of discovery, and no need for one, has been heavily criticized. People or more specifically scientists do not develop a hypothesis at random or by mystical intuition. It is often developed through reasons and arguments. Therefore, scientists have questioned whether a theory is derived from some creative intuition or by some form of inductive reasoning. In the Enlightenment era, the British philosopher John Locke (1632–1704) argued that everything we learn about the world is from our experiences, and we are not born with innate ideas. This view has been supported by many

philosophers and practitioners (from various fields) ever since. Scientists and philosophers find it hard to accept that theories can be developed *just like that*. Most of the time, development of a hypothesis is done inductively; indeed the term *hypothetico-deductivism*, which was suggested to deal with the problem of induction, is still very much dependent on induction. Hence, it is not a solution to the problem of induction. Therefore, the question remains as to whether initial theories or strict tests of hypotheses are possible without inductive reasoning.

Another major criticism of hypothetico-deductivism is that it cannot escape induction even in the testing stage. When a theory is not falsified, its acceptance is based on induction. If the best theory is the theory which survives severe tests, that only means that corroboration of a theory is based on inductive support. Therefore, philosophers have argued that falsification does not provide a basis for believing a theory even though Popper himself emphasized that theories are only provisional and should not be accepted as the truth. Philosophers argued that our belief in a theory is often based on its past success. This means that we are making an inductive argument to corroborate that theory. Therefore, hypothetico-deductivism includes the very problem it sets out to solve.

The limitation of data has been identified as another problem with hypothetico-deductivism. The process of testing of a theory depends very much on the quality of the theory as well as that of the instruments that are used in the test to make observations. It is very difficult to conclude that our observations have falsified a hypothesis, because this may be due to a shortcoming in the experiment or the research design. It may be the result of a hypothesis which is not appropriate or based on some misconceptions; and/or faulty observations. This problem becomes even more crucial in the social sciences (see section on Hypothetico-deductivism in the social sciences).

Philosophers have argued that deduction is a logic of criticism, but not a logic of discovery or justification. The logic of discovery is to find new ideas or hypotheses, while the logic of justification is to support existing ideas or hypothesis. Deduction, although suitable for criticism, is less suitable

for discovery and justification. Criticism only works if the reasoning is deductively valid; thus the reasoning is not *ampliative* because it allows us to say that if the conclusion is false, then some premises must be false as well. In a valid deduction the conclusion is contained in the premises, therefore it does not aid in the discovery of new hypotheses. Similarly, it does not help to justify a hypothesis. Therefore, according to the critics of deduction, the logic of discovery and justification can only be nondeductive.

Even though there has been some criticism of hypothetico-deductivism, it has been the main framework used in scientific explanation. For most of the 20th century, it was seen as the default mode, or the only way, of doing science. It has been and still is successfully used in many fields as the main approach to scientific explanation, particularly in fields that have well-defined and falsifiable hypothesis which can be tested in controlled laboratory experiments, for example high-energy physics. However, not all fields (e.g., geology and cosmology) have such well-defined hypotheses which can be tested with laboratory precision. Similarly, hypothetico-deductivism is used in the social sciences, as discussed in the following section, but it requires some adaptation to deal with the nature of theory, testing, and operationalization of variables in those disciplines. In addition, the recent development of information technology and its rapid growth in the ability to collect and process large volumes of data have challenged the dominance of hypothetico-deductivism in the pursuit of scientific explanation.

Hypothetico-Deductivism in the Social Sciences

Hypothetico-deductivism has been used in the social sciences by many. The French sociologist Émile Durkheim's (1858–1917) famous study on suicide followed a deductive methodology. Arthur Stinchcombe (1933–2018) suggested an adaptation of Popper's falsificationism for the social sciences. On his view, research starts with theoretical statements related to the phenomena being studied. From these theoretical statements, operational definitions and empirical statements are deduced. Based on these empirical statements,

appropriate tests are designed and conducted. Based on the results of these tests, the theory is refuted or retained.

Stinchcombe uses Durkheim's theory of egoistic suicide to illustrate this point. According to this theory, a higher degree of individualism causes a higher rate of suicide in a group. From this theoretical statement, an empirical statement is logically deduced. For example, from Durkheim's theory of egoistic suicide some of the empirical statements which are derived are: Protestants in France have a higher suicide rate than Catholics in France and Protestant regions in Germany have a higher suicide rate than Catholic regions in Germany. Based on the empirical statements, a researcher can make observations according to the resources that are available to him them. Stinchcombe noted that theories often include empirical statements that are impossible to be observed given the resources which are available to the researcher. The empirical statements will also guide the operationalization of the variables in the study. Observations are used to test the theory. If the observations are found to be false, then one can prove that the theory is false. If the observations are corroborative, then the theory becomes credible. Sometimes, multiple tests are used to test a theory. If observations are confirmed in multiple tests, it helps the theory to become more credible than does a single test.

John A. Clark discusses a reconceptualization of hypothetico-deductivism for educational research. He discusses the logical relationship between three levels of explanation: observation sentences, observation categoricals, and theory formulations. A theory formulation is a sentence that comprises axioms of a theory. Observation categoricals are the empirical content of a theory formulation and are directly connected to observation sentences. Therefore, observation categoricals provide a logical connection between theory and observation. In discussing the use of hypothetico-deductivism in educational research, Clark argues that refuting a theory (in areas such as education) is not as simple as in classical syllogism. For example, given a theory, T predicts and observation, O , if the predicted O does not happen, then T will be rejected. However, if a conjunction of theories (T^1 – T^4) implies an observation O , when O is not

observed, which part of the conjunction needs to be revised or rejected cannot be determined by logic but by pragmatic judgment. Such pragmatic judgment is important when using hypothetico-deductivism in education.

Philip S. Gorski has criticized the use of hypothetico-deductivism in the social sciences, particularly in sociology. In hypothetico-deductivism, a single counterexample is enough to reject a theory, but, this hardly happens in the social sciences (or any sciences). No major theory in the social sciences has been rejected in this manner. One problem with hypothetico-deductivism in the social sciences is the notion of universal law which forms the major premise. Gorski argues that in sociology there has not been a universal law which can serve as the premise for deductive argument. He maintains that even the reformulation of hypothetico-deductivism in sociology will result in failure. Recognizing this problem, several social scientists have suggested adapted versions of hypothetico-deductivism. In social sciences, theory and observations are related and they influence one another. Theories can function as the lenses that are used to see the social world. The use of different theories will influence different interpretations of data. Since all observations are necessarily interpretations, we are not observing reality directly and theories cannot be refuted conclusively. Furthermore, some social scientists have argued that social theories are only capable of specifying the probability of certain outcomes. Hence, the theories are only falsified probabilistically.

INDUCTION

Induction is one of the two approaches of human reasoning or theory development identified by the philosophers of ancient Greece. (The other one is deduction, which draws out exceptionless consequences of given premises and is sometimes said to be an argument from the general to the particular.) Although some philosophers have proposed other ways of reasoning, such as abduction, the most popular textbooks of logic today continue to emphasize the two-approach theory of reasoning. This entry examines the definition of induction, its historical development, the problems associated with its use as method, its modern and contemporary forms, and the various models of induction used in scientific inquiry.

Induction Defined

The traditional definition of induction was proposed by Greek philosopher Aristotle (385–323 B.C.E.). His book *The Organon* (*The Instruments*) depicts induction as “an argument from the particular to the universal.” The prominent English philosopher John Stuart Mill (1806–1873) followed Aristotle’s thinking and defined induction, in his book *System of Logic*, as “the operation of the mind, by which we infer that what we know to be true in a particular case or cases will be true in all cases which resemble the former in certain assignable respects.” That line of definition remains in use by the influential *Oxford English Dictionary*,

which defines induction as “the process of inferring a general law or principle from the observations of particular instances (opposed to deduction).”

The logician Rudolf Carnap (1891–1970), however, classified all nondeductive reasoning as induction. This Carnapian approach holds that the only characteristic of induction is that its conclusions are not logically guaranteed by its premises. The premises only provide evidences to increase the probability of the truth of the conclusions. Widely used textbooks are normally seen as reflecting the broadest consensus among researchers in a field. Two such logic textbooks, Irving Copi and colleagues’ *Introduction to Logic* (in its 14th edition at the time of this writing) and Patrick Hurley’s *A Concise Introduction to Logic* (currently in its 13th edition), both use the broader Carnapian definition of induction and include analogy as a type of induction.

Proponents of induction claim that the idea of induction is to learn from experiences: people notice patterns and repeated phenomena in their lives and make projections about those patterns and phenomena in other places or in the future. Inductive scientists observe and measure individual objectives and phenomena, and then generalize those observations and measurements into educated guesses—in other words, hypotheses. Those hypotheses that are substantiated through sufficient testing and confirmation are called *theories* and are used to guide human understandings and behaviors. Australian geologist Karl Wolf, in a letter to the editor of the *International Journal of General Systems*, *Hypothesis versus Theory*:

Part of a Hierarchy of Truth (published in issue 5 of the journal in 2007), described the process as a journey along the sequence or hierarchy of truth, from problem, idea, concept/principle, hypothesis, to theory and eventually natural law, each latter step containing more reliability, accuracy, validity, and predictability than the former step. Other theorists or philosophers who place more emphasis on deductive thinking, such as Robert Dubin, author of the popular book *Theory Building*, define hypotheses as empirical indicators or predictions of theories, which can be observed and empirically tested. Hurley called the latter empirical hypotheses and the former theoretical hypotheses.

The Early Development of Induction

Although Aristotle probably provided the earliest definition of induction, he did not invest as much time and energy discussing induction as he did in discussing deduction and his famous syllogisms. Inspired by the development of Greek medical science, the philosopher Epicurus (341–270 B.C.E.) and his followers adhered to induction and argued that reasoning based on similarities among phenomena, that is, induction, was the only instrument for determining the laws of nature. In inductive reasoning, they believed, exhaustive listing of the members of a class was unnecessary. It should suffice if both similar and different facts were examined.

The statesman and philosopher Francis Bacon (1561–1626) has been widely considered as the most prominent advocate of induction. In his book *Novum Organum Scientiarum* (translated as the *New Instruments of Science*), Bacon criticized the deductive method, which had dominated the medieval era (represented by the Aristotelian syllogisms), as useless in scientific exploration. He argued that the syllogisms were not the fundamental principle of science but a tool to force people to agree with a conclusion. No new findings were obtained, as all information in the conclusion was contained in the major premise. Scientists' only hope, he said, was in induction. He further proposed three methods to identify causal relationships in phenomena, such as a listing table of presences and absences. Bacon is deemed the founder of the theory of experimental methods.

Charles Darwin (1809–1882), who established the theory of biological evolution, stated that his own work was based on the use of “the true Baconian method.”

John Stuart Mill (1806–1873) inherited Bacon's criticism of deduction and the idea of listing tables of presences and absences. He further developed his own five methods of scientific discovery to replace the unreliable traditional induction methods such as simple listing or incomplete listing. The five methods, designed to identify causal relationships, are described in his book *System of Logic*. The first, *method of agreement*, is used to find out the only factor that appears in all instances that the result appears (necessary cause). If in two or more instances the phenomenon under investigation had only one circumstance in common, wrote Mill, the circumstance in common was the cause of the phenomenon. When two or more circumstances are present in all instances when the phenomenon appears, however, the method of agreement cannot identify the cause. The second method, *method of difference*, may then be needed to find out the only circumstance that is absent in all instances that the result disappears (sufficient cause). The third method, the *joint method* of agreement and difference, is used in the following situation: in an instance the phenomenon under investigation appears and in another instance the phenomenon disappears, and both instances have all other circumstances in common except one, which is absent in the instance when the phenomenon disappears. The exceptional circumstance is therefore the (necessary and sufficient) cause of the phenomenon. Mill treated the joint method as a new and separate one, but later logicians have held that it is actually just a combination of the method of agreement and the method of difference. The *method of residues*, the fourth, tells researchers to find out all circumstances known not to be the cause of the result. The remaining circumstance then must be the cause. The method relies heavily on the accuracy of the existing literature that helps identify the circumstances known not to be the cause of the phenomenon under investigation. The fifth method, that of *concomitant variation*, is to find, from among a group of circumstances, the one that changes together with the result. The circumstance concomitantly varying with the result

is therefore the cause of the result. The method of concomitant variation needs to identify and get rid of the influences from the confounding circumstances that vary coincidentally with the cause.

Mill's five methods were later improved by English statistician Ronald A. Fisher (1890–1962). Fisher added statistical tests to them and turned them into the modern scientific method of experiment, which is still a powerful instrument in both natural and social scientific research. The key assumption of experiment and induction, said Mill, is the existence of a universal law behind the phenomena, such as the law of causation.

The Problems of Induction

In their debate with the Epicurean philosophers, the Stoic philosophers, who flourished in the Hellenistic period, developed their criticism of induction. They argued that induction was not a valid reasoning in form, which allowed human beings to inference from phenomena in their experiences to phenomena outside of their experiences. They pointed out that induction implied an assumption: hidden phenomena are similar to phenomena that were apparent or experienced. That assumption, serving as the major premise, actually turned induction into deduction. The Stoic philosophers further denounced induction as impossible to be conducted, because partial listing of the members of a class was insufficient and complete listing of those members was infeasible.

British philosopher David Hume (1711–1776) was the thinker who conspicuously drew attention to the problems of induction, which he stated in two forms: the logic problem and the psychological problem. He described the logic problem of induction with an example: because the sun had risen every day so far, one could not be absolutely sure that it would rise again the next day. People could not reason anything from instances repeated in their experiences to instances outside of their experiences, no matter how great the number of times the instances occurred in their experiences. Those instances in experiences, Hume believed, could not even help to make an inference on the probability of the other instances that people had not experienced. In the statement of the psychological problem, Hume explained the cause of the logic problem in the human mind.

The human being, he said, has a critical internal mechanism to generate associations on the basis of repetitions and maintain expectations of the instances that they have not experienced. Human beings cannot survive without such a mechanism, but the expectation produced through that psychological mechanism is not valid. Hume's criticism of induction, British philosopher Bertrand Russell pointed out, casts huge doubt on the description of the empirical procedures of scientific research. The question of induction actually led Hume himself to become a skeptical philosopher, doubting whether or not human beings truly have the capability to know the world.

Russell echoed Hume's questioning of induction in his *The Problems of Philosophy*, but it was Karl Popper (1902–1994), who made the questioning conspicuous again. Popper's criticism of induction was based on the Stoic point of view and Hume's logical and psychological problems of induction. The traditional question of induction, Popper said, is that no justification can be established for the belief that the future will be like the past. Without such justification, inductive inference is impossible. Also, to make an inductive reasoning valid, people must first establish an axiom of induction, stating something such as "Characteristics observed in many individuals in a population can be generalized to that population." Such a principle is hard to establish. Even if it is established, it then will be used to justify all inductive reasonings and therefore turns those inductive reasonings into deductive reasonings. Popper wrote that Kant's viewing induction as containing a priori validity was clever but nevertheless wrong to solve the problem of induction. Induction essentially states that the future is quite possibly the same as the past. Since it assumes too much about the future, it is actually not a reasoning method. The commonsense theory of knowledge, which assumes that everything enters our knowledge system through the human senses, was therefore invalidated for Popper. His solution was to totally reject induction and build a theory of scientific inquiry based only on deduction, that is, the method of falsification.

Popper's falsification method holds that universal statements cannot be generated from or proved by particular statements but can be rebutted by falsifying a particular statement deduced from it.

Scientists boldly propose hypotheses on issues of interest and develop theories. Good theories have more content and stronger explanatory power, while poor theories both contain and explain less. Scientists then test those good theories in an effort to falsify them. If a theory goes through a series of tests and cannot be falsified, it then enters the knowledge system. Induction therefore has no place in the theoretical construction method conceived by Popper. He went so far as to state that there is no such thing as induction.

Modern Forms of Induction

Despite Popper's total rejection of induction, modern logicians still uphold induction as a valuable tool of reasoning and scientific inquiry and continue to develop it. At the same time, current popular textbooks of logic adopt Rudolf Carnap's idea and expanded induction by putting all uncertain reasoning into this category. In Patrick Hurley's *A Concise Introduction to Logic*, for instance, induction includes not only the traditional inductive generalization from particulars to the general but also analogy, predictions about the future, arguments from authority, arguments based on signs (anticipating a sharp curve when seeing a sharp curve sign on the interstate), and so on. Hurley defines an inductive argument as one whose premises support the conclusions in a way that it is improbable (as opposed to impossible for deduction) for the premises to be true and the conclusions to be false. The common characteristic for all inductive reasonings, said Hurley, is that their conclusions all go beyond the contents of the premises.

Analogy is the inference from one particular to another particular that shares a reasonable amount of similarities with the former. The standard format of an analogy is as follows: A has attributes of a, b, c, and d; B has attributes a, b, and c; therefore, B probably also has attribute d. Since in most situations A and B should be in a category whose members all share those similarities, Hurley holds that analogy is closely related to traditional induction. The inference first unconsciously goes from A to that category along an inductive line, and then goes from the category to B, along a deductive line. The number of the similarities shared between A and B and the relevance of those

similarities determine the strength of an analogical reasoning. Legal research in common law systems, such as the law system in the United States or in the United Kingdom is, according to Hurley, essentially analogical. Legal arguments cite precedent cases that share most similarities with the case in question and request similar legal decisions. Moral reasoning, a process similar to legal research, is mainly analogical as well. Irving M. Copi and colleagues maintain that consumer decisions are also very much made through analogies. Consumers like to buy new products from manufacturers whose products they have used and felt satisfied. With analogies they reason that the new products should quite possibly also be satisfying. Every analogical inference, write Copi and colleagues, bases itself on one or more similarities of two things that serve as the subjects of the premises and the conclusion.

In their textbooks, both Copi and colleagues and Hurley label Mill's five methods as the second type of induction, which evidences that the five methods are not outdated in human reasoning since the derivation of the experimental method from them.

Probability and statistics are now well known as a *central topic of induction*. The probability theory states that when all events (the population) are independently and identically distributed (IID), or when every element in the population has exactly the same probability to be taken in the sample (probability sampling), the probability of one event (an element) in the population or sample happening can be calculated. Statistics are measurements of attributes in a sample of events taken from the population. Researchers then estimate the parameters in the population based on those statistics. The process of inferring from the sample (a group of particulars) to the population (the general) exemplifies the classical form of induction. Those statistical inferences contain errors, and the errors—called *sampling error in statistics*—are determined mainly by the sizes of the IID samples. Those inferences are also conducted at different levels of confidence. Higher levels of confidence are normally associated with more ambiguous predictions. In the social sciences, researchers usually choose 95% as the confidence level.

Statistical inference can be nonparametrical or parametrical. Nonparametrical statistical inference makes no other assumptions of the data

distribution beyond the IID assumption. Non-parametrical inferences are less sensitive to the information in the data, compared with their parametrical counterparts, and can only be used to infer simple relationships of a few variables. Parametric statistical inferences assume, in addition to the basic assumption of IID, that the data are normally distributed (generally containing more than 30 elements in a unit of analysis, and the data contain measurements at the interval or ratio levels). Parametric statistical tests can identify complicated relationships and are more sensitive to capture detailed information contained in the data. In modern social scientific research, advanced parametric statistical models such as structural equation models, hierarchical linear models, and multivariate time series models are often used to infer complex relationships from the samples to the populations. The truth of statistical inference is, of course, probable, at different levels of confidence, rather than absolutely guaranteed.

Although not yet included in many textbooks, the new concept of *big data* research is another form of induction. With the advancement of computing technology, an enormous amount of digital data can now be created and archived. The emerging research field of data science (also called *machine learning* in computer science, *data mining* in business or marketing research, and *big data* by many other people) analyzes those data, identifies patterns, and makes predictions. Big data analyses have comparatively few theoretical frameworks or hypotheses as guidelines for the analyses, and so the analyses are largely random-fishing and inductive in nature. The data, normally with their gigantic volume, are drawn from large, although perhaps not representative, samples or even from the populations. Big data analyses have been applied both academically and practically. In academic research, the combination of traditional social science research and data science analyses produces the area of computational social science research. In practical research, one of the major services of the leading database companies, such as Axiom, Epsilon, and Experian, is to provide big data analyses to help businesses better understand their customers' lifestyles, purchasing patterns, and needs in the near future. It is now common that new car purchasers receive car insurance mailers, or new house owners receive

furniture catalogues immediately after their purchases. Allegedly, a company identified a pregnant teenager by analyzing the commodities she had recently purchased and sent her mailers on baby products before her parents had even noticed the pregnancy.

The Inductive Models of Scientific Inquiry

Rudolf Carnap (1891–1970) is a major representative of the approach of induction. In Carnap's writing, natural sciences are described as *inductive sciences*. The process of scientific inquiry is a process in which scientists make precise observations (this step is viewed as the foundation of science), conduct experiments, and then generalize to build theoretical hypotheses and theories. In inductive inference, he said, scientists investigate a whole population based on one or more samples picked out of the population, possibly referring the statistical approach that is widely used in scientific studies today.

Inductive scientists always start from direct observations of particular facts, with the belief that only facts are available to observe. Patterns of the facts emerge in the observations and lead to conceptualization, definition, and classification (categorization) of those facts. The products of those conceptualizations—concepts—serve as bricks in the building of knowledge. Theoretical hypotheses connect the concepts and, after substantial testing, enter into the knowledge system as theories or laws, which provide guidance to understand other facts with similar patterns. An example of this inductive theory-building process is George Homans's sociological theory-building model, which contains three steps: First, sociologists observe how people behave in different groups; second, such behaviors are conceptualized and generalized; third, other groups are included in the study to confirm or improve the concepts and generalizations. Scientists in many different fields have embraced the inductive tradition, despite the major criticism that induction attempts to generate knowledge about the group, or the future, based on truth gained from particular elements of the group, or on the past. Some scholars believe that behaviorism, a school of psychology, also tends to use inductive generalizations based on substantial analyses of behaviors of the

particular subjects. Marketing researcher Gordon Foxall even claims that only inductive thinking is useful to study human behaviors.

Some social scientists adhering to inductive thinking embrace Carl Hempel's inductive-statistical (I-S) model. The I-S model is a derivation and modern version of Hempel's deductive-nomological (D-N) model. The D-N model consists of a law-like statement, an antecedent condition statement, and a conclusion deduced from the two premises. The I-S model simply changes the law-like statement into a statistical lawlike statement. Although deductive in its form, it is considered inductive by logicians because the truths of the premises, the statistical lawlike statement, and the antecedent do not guarantee the truth of the conclusion. The statistical lawlike statement, however, should state a relationship that has high probability to happen. An example of Hempel's I-S model could be:

Statistical law: If the volume of media coverage on an issue increases, people will very likely think of that issue as more important.

Antecedent: The volume of media coverage on education has increased.

Conclusion: People will very likely think of education as more important.

Wesley Salmon's statistical relevance (S-R) model is derived from Hempel's I-S model but has a more generalized form. Instead of claiming that the statistical lawlike premise should state a highly probable relationship, Salmon believes that the statistical lawlike statement can be any set of statements as long as they can provide a basis for inference of the probability of the conclusion, no matter how small the probability.

The invention of statistics, stated Ronald Fisher, had made induction as strict as, if not more than, deduction. The traditional thinking was that deduction was more accurate than induction because deduction only revealed the implications contained in the axioms, but induction generated new knowledge based on observations and deduction did not. Fisher, however, pointed out three factors that statistics made induction stricter than it had been thought previously. First, statistics led to more exact calculation of the observed data; second, the advancement of the experimental

method could generate better data for observation and calculation; and, third, statistics provided more sophisticated understanding from samples to populations or from the particulars to the general. Fisher also believed that it was induction, not deduction, that needed hypotheses as guidance to interpret the data.

Marketing researcher John O'Shaughnessy has described how induction is widely applied in scientific research in six steps: First, the scientists generate perceptual experiences about the topic under study by using observation. Second, by using definition and classification, the scientists sort out in order the facts that they have collected through observation. Third, inductive generalization is performed: The scientists make inferences (hypotheses) to a broader category based on the facts observed and analyzed. Then in the fourth step, the scientists test the generalized hypotheses by using observation again. In the fifth step, hypotheses that have withstood such testing are developed into theory, or law (the latter is more certain than the former), which in the next step become basis for further scientific explanations.

Copi and colleagues describe the process of scientific investigation in seven steps, mainly inductive but with deductive components. In the first step, the scientists identify the problem. In the second step, they develop preliminary hypotheses based on experiences and existing knowledge. In the third step, they collect additional facts, under the guidance of the preliminary hypotheses, to adjust and refine those preliminary hypotheses. In the fourth step, scientists formulate the formal explanatory hypotheses, which is ready to be tested. In the fifth step, scientists deduce from the explanatory hypotheses some testable consequences. In the sixth step, they test and observe the consequences, often in controlled laboratories. The explanatory hypotheses are supported if the consequences under test are consistent with predictions from those hypotheses. If the consequences under test are not consistent with the predictions, the explanatory hypotheses need to be revised and tested again. In the seventh step, explanatory hypotheses supported with intensive tests are treated as theories and applied in people's daily (or scientific) lives. In this process, Steps 2 to 4 are mainly inductive reasoning,

drawing general explanatory principles from particular facts observed by the scientists. In the fifth step, deduction is used to draw testable consequences from the explanatory hypotheses. In the sixth step, that of testing, however, induction (in the broader definition) is again used: the conclusion that the explanatory hypotheses are correct given that the predicted consequences are observed is probable, not absolute. This step's reasoning has been deemed logical fallacious by some classical logicians.

The role of induction in scientific research is also evidenced in the recent popularity of meta-analysis. Meta-analysis, by analyzing different sets of data collected in independent studies, aims to test a hypothesis or theory with more elements of data. Meta-analysis is inherently inductive and is used more and more by scientists as a strong tool in theory building or testing.

INFECTIOUS DISEASE STUDIES

Infectious diseases are disorders that are caused by microbial organisms that include bacteria, viruses, fungi, and parasites. These organisms are passed either directly or indirectly from person to person or animal to human. In fact, all eukaryotic forms of life (i.e., plants, animals, and humans) and even some bacteria (bacteriophages) are vulnerable to

invasion of an infectious organism that can lead to disease.

Infectious diseases have plagued humans since recorded history, and likely before. There are accounts of plagues (infectious diseases that infect large groups of people) during biblical times, and the Middle Ages (Black Death), the Spanish flu of 1918, and now COVID-19 in the 2020s. These plagues, also called *epidemics* (regional) and *pandemics* (global), have had major social and economic impacts on the affected populations, and with advances in modern travel technology, infections can more easily be transported globally, affecting millions in a very short period.

Statistics compiled by the U.S. Centers for Disease Control and Prevention (CDC) show that, over the last 35 years, mortality rates from infectious diseases in the United States have declined to approximately 19%. In 1980, there were approximately 41.95 deaths per 100,000 caused by infectious diseases, compared with 34.10 deaths per 100,000 in 2014. Eighty percent of infectious disease deaths were attributed to lower respiratory infections; however, there has also been a marked increase in diarrheal diseases, such as that of *Clostridium difficile* infections. HIV/AIDS is the third leading cause for infectious disease mortality, with 2.4 deaths per 100,000 individuals. There has been a shift of mortality from HIV/AIDS to the lower socioeconomic populations in the southeastern United States.

Even with significant advances in infectious disease research and therapies, the control and eradication of these diseases remain a daunting challenge. The World Health Organization has warned that infectious diseases are spreading more rapidly than ever before, and emerging infectious diseases are being discovered on a constant basis. Infectious diseases are difficult to combat for a myriad of reasons, including the emergence of new infectious diseases. Existing infectious diseases are spreading and distributing around the globe due to human activity or climate change or are being exploited for use in bioterrorism, antimicrobial resistance, and weakening public health infrastructures in countries with economic hardships. There are several major areas of research in infectious diseases, including vaccine research, hospital epidemiology and infection control, antibiotic resistance and stewardship, environmental infectious

diseases, and bioterrorism. Each of these areas of research converge around public health and safety.

Vaccine Research

The history of vaccines to be used in immunization of an individual or population most likely dates as far back as 1000 C.E. in China. The Chinese used material from a smallpox vesicle of an infected person to inoculate a healthy person. There are also accounts of inoculation with the virus in Africa and Turkey, which then spread to Europe and the Americas. However, in 1796, the English physician Edward Jenner tested cowpox to induce immunity to smallpox, which resulted in a milder form of the disease. Eventually, this practice became widespread and resulted in the eradication of smallpox. After this innovation, the French chemist and microbiologist Louis Pasteur developed the first rabies vaccine in 1885. This occurred around the time bacteriology was becoming defined as a discipline and resulted in many new developments, including vaccines against tetanus, anthrax, diphtheria, cholera, plague, tuberculosis, and typhoid.

By the middle of the 20th century, many new vaccines had been developed, and new methods for growing viruses allowed for discoveries and technologies, including the development of a polio vaccine. Following this, vaccines for measles, mumps, and rubella made great impacts on reducing the burden of these diseases.

Vaccines comprise some of the most cost-efficient preventive modalities in health care today. For every child that is immunized with vaccines on the current U.S. immunization schedule (DTap, Hib, MMR, Td, varicella, and Hep B), the effect is to save 33,000 lives and prevent more than 14 million cases of disease; furthermore, this entails a saving of about \$10 billion in direct care costs, as well as about \$35 billion in indirect costs. However, even with a well-planned vaccine schedule, roughly 42,000 adults and 300 children perish from vaccine-preventable diseases each year.

Today, there are many new techniques advancing vaccine research, with recombinant DNA technology and newer delivery methods. New disease targets are directing vaccine scientists to new paths to treat disease. One such example of a new delivery method is with the Severe Acute Respiratory

Syndrome or SARS-CoV-2 vaccine or mRNA vaccine delivery. Traditional vaccines use a microbial protein or an inactivated form of protein that induces an immune response in a host, whereas the mRNA is the genetic sequence of the SARS-CoV-2 virus spike protein that is reproduced by cells in the host. Both produce antigens that the body can use to stimulate the immune system; however, mRNA is faster to produce than the traditional vaccine. mRNA is noninfectious and is not a concern for DNA integration because it can't enter the nucleus where DNA resides. It is more cost-efficient than traditional vaccines that require expensive chemicals and cell cultures to produce. In a pandemic situation, such as that with SARS-CoV-2, the attainment of herd immunity, where enough individuals are vaccinated to protect those who are not, is the goal. Though great strides have been made to achieve herd immunity, there is still much work to be done to reach the number of vaccinated required to ensure adequate protection of the population.

Infection Prevention and Control

Epidemiology is the study of factors that determine disease occurrence in human and animal populations. Statistical methods are used to analyze epidemiological data (usually exposure-to-disease data) to attempt to understand and characterize disease outbreaks in different settings, including hospitals, cities, states, and nations. Clinicians, microbiologists, and other health care professionals (i.e., pharmacists and biomedical scientists) involved in preventative and public health care employ epidemiologic methods to gain understanding and manage various infectious diseases. Infection control in hospitals and other institutions such as prisons employ epidemiological principles to understand and control epidemics occurring at that level.

Infection prevention and control has its origins before the induction of germ theory, when in 1846, Ignaz Semmelweis, a physician from Hungary, showed that infections were caused by person-to-person spread in a labor and delivery unit in a major hospital in Vienna, Austria. To battle the infectious material being spread by clinical staff, a policy of handwashing was instated, using a chlorinated lime solution prior to contact with

patients. Additionally, John Snow, a physician based in London, intervened in a cholera epidemic in 1854 by removing a pump handle, preventing the intake of water from the pump (point source). Today, infection prevention and control departments operate in nursing homes and hospitals to derive policies, based on the basic principles of hand hygiene, appropriate handling of infectious materials, sterilization, and infectious disease surveillance to detect the beginning of a potential outbreak as quickly as possible.

Infections that are encountered in a hospital range from community-acquired infections such as methicillin-resistant *Staphylococcus aureus* (MRSA) and coagulase-negative *Staphylococcus aureus*, surgical site infections, urinary tract infections, and central line infections. Nosocomial infections (hospital-acquired infections) can occur, whereby clinical staff, in the absence of good hand hygiene practices, spread infections such as *Clostridium difficile* and multidrug-resistant organisms (MDROs) from patient to patient. Food-borne illnesses can also occur, as well as environmental causes (i.e., water towers breed *Legionella* spp.). In each of these infection types, the source and spread must be determined. Infection control practitioners use epidemiological principles to be able to determine the source of infections and employ the correct measures to get the spread under control.

An area in health care that frequently sees high levels of infection are with surgical patients. The National Health and Safety Network is a division of the CDC that has developed criteria that all infection prevention and control departments follow for the standardized identification and reporting of surgical site infections. In addition to reporting surgical site infections, routine monitoring is conducted within operating rooms and patient floors to ensure that proper hand hygiene and antiseptic technique is used when caring for these patients. Any findings of industry importance are analyzed and summarized in literature for the benefit of others within the field.

Environmental Infectious Diseases

The environment is often a significant contributing factor in the spread and occurrence of infectious diseases, both regionally and globally. Climate

change is emerging as a significant driver in the activity of infectious diseases, especially in the areas of vector-borne diseases, such as dengue, malaria, hantaviruses, and arboviral diseases. When examining the chain of infection, environment often has a key role in reservoir maintenance and route of transmission through air, water, and food.

During the 20th century, the world experienced large-scale anthropogenic changes in the environment. Intensive farming methods in conjunction with trade and travel are associated with the emergence of bovine spongiform encephalopathy (mad cow disease), foot-and-mouth disease, and viruses such as Nipah. Avian influenza is currently the greatest concern for global human health, because it can be transmitted from bird to human, as frequently happens in areas of Asia such as China or Indonesia. The sizes and proximities of flocks of poultry that are currently being kept for agricultural purposes would never occur in a natural setting. The proximities allow for the rapid spread of avian flu strains that can mutate and cause disease in humans more efficiently than in nature. Another example of infectious diseases spreading in the environment due to anthropogenic forcing is in Africa, where people hunt bushmeat that has had contact with many other types of animals carrying viruses. It is believed that bushmeat hunting accounts for the introduction of highly pathogenic viral diseases such as HIV/AIDS and Ebola.

Dam building and irrigation projects that oversee distribution of freshwater supply have introduced diseases such as schistosomiasis, Rift Valley fever, malaria, filariasis, onchocerciasis (river blindness), and Japanese encephalitis, to name a few.

It is important to understand these factors and how the environment plays a role in the emergence and spread of infectious diseases. Determining the causal links between climate change and disease emergence is difficult but requires a collaborative approach across states, provinces, and nations. It requires a variety of tools and expertise from many disciplines. Research involved in studying these outcomes will potentially result in better surveillance methods, detection, and collaborative response.

An example of research being conducted on infectious diseases and climate change is with hantaviruses. Hantaviruses are rodent-borne emerging

viruses. They cause two types of human disease: hemorrhagic fever with renal syndrome in Asia and Europe and hantavirus cardiopulmonary syndrome in the Americas.

Climate change, or global warming, has an impact on reservoir host behavior. Since most hantavirus infections occur in the warmer months, and rodent reservoirs are expected to migrate northward, the geographic distribution and frequency of infections is expected to increase in the next few decades. This phenomenon has already been observed in West-Central Europe, where there has been an increase in Puumala hantavirus outbreaks, in parallel with elevated average temperatures. Higher temperatures will lead to human activity that will increase exposures through aerosolized excreta.

Dams can be very useful to stabilize water availability and provide power but can also usher in disease outbreaks. In 1986, the Diama Dam was placed on the Senegal River to support agricultural expansion through water stability and prevention of saltwater intrusion. A few years after it was installed, a significant increase in human schistosomiasis, an infectious disease caused by a parasitic worm, was detected. The precise mechanism for the increase is not well understood but is believed to have been caused by the interaction of economic, epidemiological, and ecological factors. Dams have been associated with schistosomiasis for many years, and frequent problems occur around dams installed in Africa. Studies are being conducted to test the theory that introducing an abundance of *Machobrachium* species prawns will facilitate the natural reduction of schistosome snails that host the parasite, leading to lower incidences of disease in humans. This will help balance the need to use dams for power sources and control in areas endemic to the parasite.

Antibiotic Resistance and Stewardship

Antibiotic resistance is a very important problem in the study and control of infectious diseases. It is a significant contributor to mortality and morbidity, prolonged hospital stays, and increased health care costs. Simply put, overuse and inappropriate use of antibiotics results in the development of antibiotic resistance. The vast majority of

antibiotic use occurs in primary care settings and nursing homes, but it is a significant problem in hospitals, where MDROs are most likely to develop. The CDC has classified several bacteria as causing urgent, serious, and concerning threats. These resistant bacteria, such as MRSA, ESBL, and vancomycin-resistant enterococci, result in increased health care costs. Antibiotic stewardship is a means to direct and offer guidelines for the judicious use of antibiotics in hospitals to help reduce or eliminate the problem of antibiotic resistance.

Antibiotics first emerged with the discovery of penicillin by Sir Alexander Fleming in 1928. Penicillin was very effective in controlling infections among World War II soldiers. Yet, shortly after the war, penicillin resistance began to emerge. By 1962, the first case of MRSA was identified in the United Kingdom, followed by the United States in 1968. Now, resistance to nearly all antibiotics has been observed in the clinical setting. From the 1960s to 1980s, the pharmaceutical industry introduced new antibiotics, but subsequently little research and development has been implemented.

Bacteria acquire resistance to antibiotics by inheritance from relative bacteria or through non-relative bacteria by a circular DNA organelle called a *plasmid*. When acquired by a plasmid, a horizontal gene transfer causes antibiotic resistance to be passed between different species of bacteria. Resistance can also occur spontaneously through mutation. Antibiotics kill drug-sensitive bacteria that would compete for resources, resulting in the proliferation of resistant bacteria.

One of the main drivers of antibiotic resistance includes inappropriate use, or clinicians prescribe an antibiotic without investigating the species type or sensitivity of the bacteria to a particular antibiotic. Frequently, infections for which antibiotics are prescribed are actually viral and not bacterial in nature; such infections cannot be treated by antibiotics. Additionally, antibiotics that are not prescribed in a therapeutic dose but in a dose too low to be effective can promote the development of antibiotic resistance through supporting genetic alterations. These genetic alterations can lead to increased virulence and strain diversification.

Another way that antibiotic resistance has occurred is through extensive agricultural use. Globally, antibiotics are prescribed as a means of

growth enhancement in livestock. Approximately 80% of antibiotics sold in the United States are employed in livestock production to prevent infection and promote growth. It is said that treating livestock with antibiotics can lead to healthier animals and increase larger and higher quality yields. However, humans ingest the unmetabolized antibiotics when they consume animals that are treated with large quantities of the drug.

In addition to the negative effects on animal and human health, the overuse of antibiotics affects the environmental microbiome. Nearly 90% of antibiotics administered to livestock are excreted through waste and deposited in fertilizer, groundwater, and surface runoff. This inevitably increases spread of resistant organisms within the environment.

Antibiotic stewardship programs (ASPs) oversee measures within a hospital that promotes judicious use of antibiotics. They are developed at the hospital level; there is no standardized, universal set of rules for the use of antibiotics at this time. A growing number of research articles within the ASP arena indicate that antibiotic stewardship is a priority, but several research gaps still need to be addressed. Barriers to the development of ASPs need to be identified, as well as the correct actors implementing change; in addition, more work is needed on translating research into stewardship guidelines, defining outcomes, establishing an evidence-based approach for the selection of specific antibiotic regimens, and understanding the role of governmental policies on ASPs.

Research that explores ways to slow or eliminate antibiotic resistance is under way. Collaborative efforts, such as the Consortium on Resistance Against Carbapenems in *Klebsiella* and other Enterobacteriaceae (CRACKLE-1), headed by David van Duin, MD, PhD, at the University of North Carolina, seeks to understand the mechanism of resistance for carbapenem-resistant Enterobacteriaceae (CRE). Results from the CRACKLE-1 consortium showed that ST258, the primary strain of CRE *Klebsiella*, has subdivided into various strains that have distinct clinical outcomes. This data led to the creation of CRACKLE-2, which had over 60 hospitals in participation. CRACKLE-2 was a multicenter research study that collected clinical and epidemiological data on patients diagnosed with MDRO infections to

assess the desirability of outcome ranking measured at 30 days from index culture. It also characterized the MDRO species, strain type, and resistance mechanism to carbapenem. Research such as CRACKLE-1 and 2 will yield information that can help direct hospital Antibiotic Stewardship programs and infection control practitioners to more adequately address the proclivities of CRE antibiotic resistance and improve patient outcomes while decreasing hospital costs.

Bioterrorism

Although not a new concept, bioterrorism, or the use of a biological agent to incapacitate or kill another person or group of people, is an important topic in the area of infectious disease studies. Biological agents can be spread by air, water, or food. Once infected, a victim can spread the disease to another person. Biological warfare is insidious because it is hard to detect and usually does not cause illness for several hours or days after being released.

There are several incidences of bioterrorism where an infectious disease was used during wars, as early as 600 B.C.E. In that period, people catapulted cadavers, excrement, and animal carcasses riddled with germs into enemy camps to incapacitate the enemy and win conflicts. Pollution of wells occurred in several European wars, the American Civil War, and also in the 20th century. The Japanese military used plague as a biological weapon by inducing transmission of the disease through infected fleas to rats in a laboratory setting. They then released plague-infected rats in Chinese cities to initiate an epidemic. This backfired, though, and about 1,700 Japanese troops died after being exposed. German medical researchers infected prisoners with *Rickettsia prowazekii*, malaria, and hepatitis A virus at the time of World War I. In the United States, a biological warfare program was initiated in 1942 by the War Reserve Service. Today, the government entity responsible for bioweapons research and development is at Fort Detrick, Maryland (U.S. Army Medical Research Institute of Infectious Diseases [USAMRIID]).

In 1972, the United Nations General Assembly adopted the Convention on the Prohibition of the Development, Production and Stockpiling of

Bacteriological (Biological) and Toxin Weapons and on Their Destruction (BWC). Under this treaty, any development, production, or stockpiling of pathogens or toxins among member countries is prohibited. It required all parties involved to destroy any existing stockpiles, delivery systems, or equipment within nine months of the treaty being signed. In the United States, President Richard M. Nixon signed an executive order in 1969 and 1970 to terminate the offensive biological weapons program. Along with this order, the United States created a policy to ban the use of biological weapons, including toxins (e.g., botulism). The only caveat was to allow research efforts to continue for countermeasures to potential attacks, including vaccines and antisera. Between May 1971 and February 1973, the entire stockpile of biological weapons was destroyed, overseen by the U.S. Department of Agriculture, Nature Resources of Arkansas, Colorado, and Maryland. USAMRIID continues to conduct research for development of medical defense for the military in the event of an attack. The research conducted is considered open and is not classified.

The threat of a biological attack is always present, and the medical community, as well as public health organizations, must be diligent in surveillance, epidemiology, and countermeasures for mass hysteria if a biological weapon is used on the population. To understand the effects of biological weapons on a population, modeling is used. These models look at the worst-case scenarios of exposures for millions of human casualties or fatalities. Though simulations are not perfect solutions, they do help form hypotheses and raise questions on preparedness that could not be done without the models.

Conclusion

There are many areas in health care and the environment with which infectious diseases intersect, and ongoing research is necessary to continue to educate not only people in health care and science fields but also laypersons. A thorough understanding of the pathophysiology and mechanisms of infectious diseases is the foundation for all other endeavors, such as vaccine research, antimicrobial resistance, environmental health, infection

prevention and control, and bioterrorism research. Though all these areas are important, antimicrobial resistance and vaccine research are of the highest priority because quarantine and nonmedical control measures are effective, but without a means to treat infections, deaths would continue and potentially be uncontrollable.

INFERENCE

Inferences drive scientific inquiry. Inferences are instances of reasoning that take some given evidence as input and yield, as output, a judgment, or statement. Prominent outputs for scientific inference concern statistical associations, cause–effect relations, and the pursuit worthiness of research programs. Especially famous inferences include Euclid’s proof of the Pythagorean theorem from various postulates and diagrams, Archimedes’ (legendary) discovery of the law of buoyancy while observing his body displace water from a tub, Albert Einstein’s inference from a thought experiment about a man falling freely through space inside an elevator to the equivalence of gravitational mass and inertial mass, and Alpha-Go’s strategic inferences to defeat grandmaster Lee Sedol in four games of a five-game Go match.

Categorizing Inference

Attending to divisions among classes of inference facilitates understanding the nature of inference. Three prominent categorical frameworks divide inferences into deductive and inductive, demonstrative and ampliative, and formal and material.

Deductive Versus Inductive

Contemporary logicians typically divide the class of inferences into deductive inferences and inductive inferences. With deductive inferences, the inputs to reasoning, or premises, purport to guarantee the truth of the outputs or conclusions. With inductive inferences, the inputs only purport to make the outputs more likely than not. For example, despite the standard terminology, the proof by mathematical induction that $11^n - 6 = 5m$ (for every positive integer n and some integer m), from the base case $11^1 - 6 = 5(n=1, m=1)$, is a deductive inference. By contrast, in their 1977 article “Every Planar Map is Four-Colorable,” the mathematicians Kenneth Appel, Wolfgang Haken, and John Koch present their computer-assisted proof of the four-color theorem from the axioms of graph theory as inductive, by virtue of its appeal to (likely harmless) probabilistic assumptions.

Deductive inferences are good (valid) when the truth of their premises precludes the falsity of their conclusions, and bad (invalid) when they do not. For example, the standard proof for the inequality of 1 and 0 from Peano’s axioms for arithmetic is a valid deductive inference, because the truth of those axioms guarantees that $0 \neq 1$. Inductive inferences are good (cogent) when the truth of their premises makes likely the truth of their conclusions and bad (uncogent) when they do not. For example, Isaac Newton’s inference, in his *Principia Mathematica*, from Proposition 5 of Book 3 (that the moons of Jupiter gravitate toward Jupiter and the moons of Saturn gravitate toward Saturn) to Corollary 1 thereof (that there is gravity toward all other planets) is a cogent inductive inference, because it depends upon the (correct) assumption these other planets also have moons orbiting them.

Demonstrative Versus Ampliative

The distinction between deductive and inductive inference resembles another distinction, that between demonstrative and ampliative inference. Inferences are demonstrative when their inputs contain all of the content or information in their outputs (and perhaps more). They are ampliative, by contrast, when the content of their outputs amplifies, or exceeds, that of their inputs. Because the premises of demonstrative inferences necessitate their conclusions, all good deductive inferences are demonstrative. There is reason to suppose that some inductive inferences are also demonstrative. For example, so-called Holmesian inferences, which infer that some theory must be correct because all alternative theories are false, seems to be both inductive, by virtue of the implicit assumption that all possible alternatives are known, and also demonstrative. Many other inductive inferences, such as Newton’s inference from Proposition 5 of Book 3 to Corollary 1 thereof and Appel, Haken, and Koch’s inference from the axioms of graph theory to the four-color theorem, are ampliative.

Although the preceding distinctions, between deductive and inductive inference and between demonstrative and ampliative inference, are helpful for categorizing specific instances of reasoning,

they are less than helpful for understanding how scientific reasoning works in practice. Three observations are salient in this regard. The first is that the preceding distinctions ignore inferences that invoke inputs that lack truth-values, because they presume that the inputs for good inferences are always declarative statements. This presumption has the unfortunate consequence, for example, that Euclid's proof of the Pythagorean theorem is a bad inference, because Euclid invokes various (nondeclarative) commands and visual intuitions about particular geometrical diagrams when presenting his proof.

The second observation, derived from the same reason as the first, is that the preceding distinctions also ignore inferences that yield outputs that lack truth-values. Yet some scientific inferences yield, as outputs, recommendations to pursue one research hypothesis or strategy rather than another. For example, given two competing models that perform equally well with respect to available experimental data, scientists sometimes infer that one model is more plausible than the other by virtue of being more robust to alterations of its parameters, their plausibility judgment is meant to recommend the one model as worthier of further research efforts—and not to recommend that the one model is more likely to be true than its competitor.

The third and final observation is that adding as input a claim to the effect that *if the inputs are correct*, then the output is correct suffices for converting any inductive inference into a deductive one and any ampliative inference into a demonstrative one. Applying the distinctions to categorize various inferences thereby depends heavily upon decisions about whether to interpret those inferences as containing implicit claims that secure their validity.

Formal Versus Material

For the sake of better understanding how scientific reasoning works in practice, contemporary logicians distinguish between formal inferences and material inferences. An inference is *formal* when its goodness depends entirely upon its logical form. Such inferences conform to formal schemes. Paradigmatic examples include *modus ponens*, which has the form *if P, then Q; P;*

therefore Q, and statistical syllogism, which has the form *N% of individuals in reference class F also belong to attribute class G; individual x belongs to F; therefore, x also belongs to G*. An inference is *material*, by contrast, when its goodness depends at least in part upon its empirical content or background knowledge. Inductive generalizations, or inferring that some characteristic of a sample holds of a broader population, are often material inferences. Consider, for example, the inference from observations that some samples of a new organic salt melt near a certain temperature and standard pressure to the conclusion that all such salt melts near the same temperature. This inference seems to conform to a formal scheme with an implicit premise that whatever is true of a representative sample is true of the corresponding broader population. But the inference is material, because determining whether the observed samples of salt are representative requires an appeal to background knowledge about variability among organic compounds of the same kind.

Classifying some inferences as material inferences helps to explain several features of scientific theorizing in practice. It helps to explain why conceptual change sometimes affects the goodness of inferences by focusing attention on the empirical content of premises. Consider, for example, the predictive inference from *this pea plant has a certain gene* to *this plant's peas will be a certain color*. This is a cogent inference scheme in the context of classic Mendelian genetics, where the concept of *gene* refers to an allele that determines an organism's appearance. But it is an uncogent scheme in the context of contemporary developmental biology, where the concept of *gene* refers to particular DNA nucleotide sequences and does not determine an organism's appearance. Classifying some inferences as material inferences also helps to explain how scientific discovery can be rational without proceeding in accordance with general rules of inquiry. Consider, for example, Hans A. Krebs's discovery of the urea cycle that converts toxic ammonia to excretable urea. Krebs's discovery relies upon stoichiometric considerations that are particular to metabolic chemistry, such as criteria for specifying the sequence of metabolic reactions and for balancing chemical equations. Insofar as the inferences responsible for his discovery are material, it is background

knowledge about metabolic chemistry, rather than any formal schema, that licenses the cogency of Krebs's inferences.

Varieties of Inference

Inferential strategies in the sciences, engineering, and mathematics are many and varied. What follows is a brief review of some strategies that are especially prominent and important in contemporary scientific practice.

Statistical Inference

Statistical inferences appeal to principles of probability or statistics. The two most dominant traditions for conceptualizing statistical inference are *frequentist statistics* and *Bayesian statistics*. Both traditions agree that likelihoods—probabilities of obtaining some result or output given the presumed truth of some hypothesis—are relevant to making inferences as the factors responsible for those results or outcomes. They disagree about which likelihoods are relevant and about how relevant likelihoods function as premises for inference.

Frequentist Statistics

Frequentist statistics, also known as *classical statistics*, involves inferring from probability statements about real or hypothetical long-run frequencies pertaining to a data sample from a population to conclusions about whether one ought to accept or reject various hypothesis about the populations from which those frequencies derive. In the social and behavioral sciences, the dominant paradigm for frequentist statistical inference is *null hypothesis significance testing* (NHST). NHST begins by specifying a null hypothesis, H_0 , to the effect that some factor makes no difference to a phenomenon of interest or that some intervention has no effect upon a system of interest. Paradigmatic examples of null hypotheses include the hypothesis that a coin is fair (and thereby does not contribute to whether flipping the coin yields *heads* or *tails*), and the hypothesis that some medicine does not reduce the symptoms of some disease. NHST contrasts the null hypothesis with a contrary alternative hypothesis, H_A , according to which the factor or intervention of

interest has a statistically significant impact upon the outcome of interest.

Given a data sample obtained from observation or experimentation, NHST proceeds by selecting a test statistic for the data—such as mean data value or variance among data values—and calculating the value of this statistics from the sample data. NHST determines the evidential bearing of this statistic upon the null hypothesis by selecting a testing rule. Testing rules determine how likely a null hypothesis should make the value of the test statistic in order for the data to not count as evidence against the null hypothesis. Each rule relate a p value to an *alpha* level, where the p value is the probability, relative to the null hypothesis, of obtaining a value for the selected test statistic that is at least as extreme as the actually obtained value, and the alpha level is some number α —typically 0.05 or 0.01—such that data count as evidence against the null hypothesis if and only if the p value for that data is not greater than α . Calculating the p value for a given data sample then permits an inference either to the conclusion that the null hypothesis is likely correct (if $p > \alpha$) or to the conclusion that the alternative hypothesis is likely correct because the null hypothesis is likely incorrect (if $p \leq \alpha$).

Whether inferences that derive from NHST are reliable is a matter of ongoing debate. So, too, are views about details of the inferential procedure for NHST. NHST is an amalgam of competing inferential procedures. The reliance upon p values derives from a Ronald Fisher's method for determining whether associations among data are due to chance. The reliance upon alpha values when testing for significance, derive from Jerzy Newman and Egon Pearson's method for determining whether prudence counsels accepting or rejecting hypotheses. Standard criticisms typically fault NHST-based inference for being incoherent, lacking principles that determine whether a test statistic is appropriate, and correlating low p values with high degrees of support for alternative hypotheses.

Bayesian Statistics

Bayesian statistics involves inferring from probabilities pertaining to a data sample D and various hypotheses to a conclusion about the degree to

which the data supports one of those hypotheses. These inferences involve three substantive premises: a statement about the prior probability of some hypothesis of interest, $\Pr(H)$, which indicates how likely the hypothesis is in relation to existing evidence; a statement about the probability of the data in relation to the hypothesis of interest, $\Pr(D|H)$, which indicates how likely it would be for the data to obtain if the hypothesis were true; and a statement about the probability of the data itself, $\Pr(D)$, which is the straight sum of products between the prior probability of one of several exclusive and exhaustive hypotheses H_i and the probability of the data in relation to that hypothesis (such that $\Pr(D) = \sum_i \Pr(D|H_i) \times \Pr(H_i)$). These premises support a conclusion about the degree to which the data support the hypothesis of interest, $\Pr(H|D)$, by virtue of a theorem from probability calculus known as *Bayes' Rule*.

$$\Pr(H|D) = \frac{\Pr(H) \times \Pr(D|H)}{\Pr(D)}$$

Consider how Bayesian statistical inference compares to NHST-based inference in the case of determining whether a coin is fair. Let the null hypothesis be that the coin is fair: $H_0 := \Pr(\text{heads}) = 0.50$. Suppose background evidence excludes all but one alternative hypothesis, According to which the coin is slightly biased toward heads: $H_A := \Pr(\text{heads}) = 0.55$. (Perhaps the coin is known to originate from one of two machines.) Let the relevant experiment be flipping the coin 1,000 times. Let the data show that the coin lands on heads exactly 528 times. Then $\Pr(D|H_0) \approx 0.0056$ and $\Pr(D|H_A) \approx 0.0095$. Supposing that the null and alternative hypotheses are equally likely, $\Pr(H_0) = \Pr(H_A) = 0.5$. Since $\Pr(D) \approx 0.0076$, Bayes' Rule entails that $\Pr(H_0|D) \approx 0.3712$ and $\Pr(H_A|D) \approx 0.6288$. Bayesian statistical inference therefore concludes that the coin is more likely biased than fair. The NHST procedure, by contrast, relativizes inference to a testing rule. Let the rule be that H_0 is likely correct if and only if the p value for the experiment is not greater than 0.05. Since the p value equals $\Pr(D|H_0) = 0.0056$, the NHST procedure entails that there is no significant disagreement between the data and the null hypothesis, and so the coin is likely fair. (If the α value were selected to be 0.01 rather than 0.05,

or if the coin had landed on heads more than 528 times, the same procedure would entail that the coin is likely biased.)

Causal Inference

Statistical inferences are vehicles for theorizing about statistical associations among factors in some system or population of interest. However, they do not yield reliable conclusions about causal connections. Statistical inferences lack power to discriminate between one factor causing another and one factor being coincident effect of some other common cause. They also do not address issues about what would happen to a system or population if some putative cause were different. Several approaches to causal inference aim to overcome these limitations of (mere) statistical inference. The two most dominant approaches to causal inference are the potential outcomes approach (POA) and the structural modeling approach.

Potential Outcomes Approach

POA involves inferring from experimental data about a system of interest to conclusions about the causal effect of one factor relative to another. The experimental data typically derive from comparing the effects of a test intervention upon some factor of interest to the effects of an alternative control intervention, and the causal inference is a matter of calculating the causal effect of the test intervention relative to the control as a difference between the effects of the test and control, respectively, after multiple interventions. For example, if the system of interest is the human body and the effect of interest is alleviation of some bodily ailment, if a sample of people with headaches who take a specific medicine typically have headache relief within an hour while a sample of people with headaches who take no medicine typically have no relief within an hour, and if the samples of people are otherwise similar, POA might infer that taking the medicine has a causal effect relative to not taking any medicine. (Determining whether the inference is warranted typically involves using frequentist statistics to determine whether a causal effect is statistically significant.)

Whether data warrant an inference about causal efficacy depends, according to POA, upon a variety

of considerations. The calculated causal effect should be statistically significant. The composition of the test and control samples should be unbiased. The samples should not differ with respect to other factors that might be causally efficacious. They also should represent the population or system of interest. Frequentist statistical inference with respect to a null hypothesis about expected causal effect, random sampling from a population of interest, and randomization with respect to potentially confounding factors are standard tactics for satisfying these desiderata.

Structural Modeling Approach

The structural modeling approach to causal inference involves using causal hypotheses to build a statistical model, testing the hypotheses in the model, and evaluating test results to infer to a conclusion about whether the model is valid. Causal hypotheses are speculations about cause-effect relations among different factors within a population or system of interest. These speculations are based upon background knowledge and available correlational data, and combining them yields a model for a structure of cause-effect relations. Testing a model involves various statistical methods, such as parameter estimation and goodness of fit, to determine how well the model describes available data. Such tests aim to determine whether a model—and its associated causal hypotheses—is valid in one of four senses, namely, whether the model supports claims about covariation among various factors, whether it represents causal relations, whether alternative cause-effect constructs yield consistent results, and whether the model generalizes to other populations or systems.

Heuristics

When the need to make inferences is pressing, limitations of time, knowledge, and computational power favor fast and frugal inferential strategies over provably reliable ones. These strategies often take the form of heuristics. Because the reliability of these heuristics—their capacity to produce good inferences rather than bad ones—often depends upon the context in which they occur, the heuristics are often strategies for material inference and therefore relatively limited

in scope. Consider, for example, the task of programming a computer capable of inferring appropriate moves for games of chess. The rules of chess impose time limitations for completing each game of chess, and processor capacities limit the speed and number of calculations any computer is able to perform. Because of these limitations, modern chess programs typically rely upon heuristics that infer appropriate moves by evaluating only some available information about the chessboard, such as the relative value of remaining pieces, the number of attacking pieces in the board's center, and the number of pieces in position to attack the opponent. The success of these heuristics depends not only upon the astounding computational powers of modern computers but also upon the high number of constraints that chess imposes in comparison to, say, the constraints relevant to programming an autonomous vehicle to navigate dense urban traffic—such as a relatively small environment, a relatively limited number of moves all of which have well-defined consequences, and a single goal.

Even when the need to make inferences is not pressing, there are reasons to favor inferential strategies that are not directed toward correctness. Inferences at the frontiers of inquiry often are directed toward discovering appropriate next steps for research rather than producing conclusions that are likely to be true. Such inferences require ranking the potential for pursuing one line of research rather than another. Because research frontiers are typically awash with uncertainty, ranking competing courses of research often involves heuristic strategies for inferring that much of the information available about a research topic is likely irrelevant. For example, rather than read thousands of article abstracts, one might use the heuristic *only read articles that contain specific keywords* to infer that many available articles in one's research discipline are likely irrelevant to one's research project. Similarly, rather than attempt to justify whether a particular research procedure is worth developing, one might use the heuristic *develop any research procedure that produces surprising results*.

Because research funding is limited and research efforts devoted to one line of inquiry preclude devoting attention to others, determining whether a model or theory at a research frontier is worthy

of further development also often involves heuristic strategies of inference. Consider, for example, a brief history of the liquid drop model for atomic nuclei. In the late 1920s, the Russian physicist George Gamow proposed to treat atomic nuclei as drops of water whose constituent particles are held together by surface tension. Gamow used his model to explain the nuclear binding energies of different nuclei, but the model's predictions were only accurate for relatively light elements. Although Gamow abandoned his model, several European physicists continued efforts to revise and extend it. These efforts eventually led to the discovery of the semiempirical mass formula as well as explanations for artificially induced radioactivity and nuclear fission. But the physicists had no way to know, in advance, that their efforts would be fruitful, because the limited success of a simple model does not guarantee that revisions or extensions of the model also will be successful. Instead, their decision to develop Gamow's model likely relied on a heuristic inference from the fact that adapting an existing and well-understood modeling strategy to a new domain is more cost-effective than developing a novel or poorly understood strategy to the conclusion that Gamow's model was worth pursuing.

INFERENCE TO THE BEST EXPLANATION

Inference to the best explanation (IBE) is a type of scientific reasoning whereby the best explanation for a scientific phenomenon is accepted as the correct explanation. IBE stems from the belief that causes cannot be known with absolute certainty but are known only through highly probable theories about causality. IBE is distinct from deductive and inductive reasoning and is often considered a third type of reasoning associated with *abduction*, set forth by philosopher Charles Sanders Peirce. The terminology IBE was coined by Gilbert Harman to prevent misunderstanding as to what was being reasoned or inferred. In particular, IBE proposes that it is not the cause, as such, that is being inferred but rather the explanation for the effect. This type of reasoning happens in reverse order from basic inductive reasoning.

Terminology

Harman coined the term *inference to the best explanation* in 1965 to propose that inferences in scientific study are all extensions of one basic point, which is that humans infer reasons for effects. Harman was not the first to put forth this notion but drew on others who have called the process *abduction*, *method of hypothesis*, *hypothetical inference*, *method of elimination*, *eliminative induction*, *theoretical inference*, *explanatory inference*, and *explanation-based evidence*. Harman took a stance that this notion was the most basic form of scientific reasoning, and that other inferences, including those from inductive reasoning, could be reduced to this theory.

Forming Hypotheses

An explanation is a proposition of a reason for a particular phenomenon. While there could be unlimited number of explanations for a phenomenon, some philosophers note that a good explanation would minimally be recognized as a *cause* for the phenomenon, be *inferred* from the phenomenon, and be *plausible* compared with other possible explanations. When one is ready to accept the explanation as a likely one, it can be called a *hypothesis* and therefore, in science, is open to testing and rejection.

It is important here to recognize that each of these criteria is evaluated on the basis of likeliness but is also based on background knowledge or theoretical frameworks. The first, *causality*, remains possible only insofar as it can be backed up from inductive reasoning. A cause, after repeated observances, is deemed a cause only once it is seen as sufficiently likely, though not certain, to lead to the effect in question. For every time one drops a bowling ball and it falls to the ground, it is certain only that every time in the past it has been dropped, it has fallen. There is no guarantee that this will happen the next time it is dropped.

The second criterion, *inference*, is also determined on the likelihood that if given the effect, the cause would be inferred. Without inference, there would be two observed phenomena, but they would seem unrelated. It is the relationship to the cause that must be inferred from the effect.

Finally, the explanation must be *plausible*, particularly in relation to other possible explanations. One could say that night and day occur because the sun revolves around the earth, but given the evidence that has been amassed since Galileo, this is not likely and there are better explanations, particularly that the earth revolves around the sun and rotates on its own axis. Often, evidence from many different sources is required to explain an effect better. Some philosophers of science do not think all of these conditions are necessary for an explanation to be deemed *best*.

Reasoning to the Best Explanation: An Example

IBE is a form of reasoning that begins with examining a scientific phenomenon and seeking to understand its cause. Hypotheses are formed, and one by one are eliminated. IBE proposes that all forms of evidence should be considered to form hypotheses of cause and effect, and that the hypothesis which seems best should be accepted. It is important to note that *best* tends to be a subjective determination and is not necessarily the most statistically *likely* explanation inferred from the given evidence. Other forms of inferential reasoning, such as induction, may be employed in IBE. Pure inductive reasoning, however, is limited in that it can only test a hypothesis but is not able to reason for explanations of why effects happen. IBE proposes that enumerative induction is only a special case of inference to the best explanation and is effective only in that it eliminates other hypotheses.

A classic example that is given is the following observation:

(1) The grass is wet.

With this observation, one would immediately begin to seek explanations for why the grass is wet. One would seek to solve the puzzle of what caused the grass to be wet:

Cause → Effect

? → The grass is wet.

First, one may reason that if the grass is wet, then it must have rained. This hypothesis comes from working backward, namely reasoning that when

it rains, the grass gets wet. Therefore, we can see a relationship being formed:

(2) The grass is wet, because it rained.

Or, in cause and effect order:

(3) It rained, therefore the grass is wet.

However, this cause can never be fully endorsed, since only the effect was observed. There may be alternative explanations. Regardless of all of the inductive evidence collected that rain makes the grass wet, it only may remain a possible, perhaps even probable cause. Thus, the explanation becomes the hypothesis of the explanation for the effect.

Say, now, that one was to observe the street, and it is dry:

(4) The grass is wet, but the street is dry.

One now must revise the hypothesis, because if it rained, the street would also be wet. Now one must eliminate the hypothesis developed in (2) and seek for another explanation. One may reason that if the grass is wet and the street is dry, then there must have been a sprinkler system in the yard:

(5) The grass is wet because the sprinkler was on.

Without contrary evidence, this hypothesis explains that the grass is wet better than it rained. So, we may infer from (1) that the sprinkler was on and caused the grass to be wet. We still do not know if this is the cause with complete certainty. It is possible that there was a water balloon fight, a manual watering system, or some other cause. However, this explanation stands as the best explanation until contrary evidence is presented.

IBE in Different Fields

IBE has helped to explain the process of reasoning, especially in science, but also in common sense and other fields. The doctrine of plausibility, particularly, allows scientists to dismiss explanations that analytically or logically may be valid but lack the condition of plausibility. For example, one could claim that the rooster crows and the sun rises, therefore the rooster caused the sun to rise in the sky. While perhaps inductively this could be endorsed beyond reasonable doubt, as the rooster crows every morning and the sun rises every morning, scientists may reject this claim because it simply is not a plausible explanation.

This introduces an element of subjectivity to science, in that no explanation is completely certain and objective. An explanation must remain falsifiable, because it is always open to revision and a possible better explanation may exist. IBE allows inferred explanations to be tested, critiqued, and improved upon. Perhaps most notably, IBE has been used to explain Darwin's process of developing the theory of natural selection. Evidence found in biological diversity does not particularly entail the theory of natural selection outright. Rather, natural selection has been accepted by many to provide the *best* explanation for that evidence.

The theory has applications in other fields as well. Take a criminal trial, for example. The burden of the prosecution is to present evidence, beyond reasonable doubt, that the accused has committed the crime. The prosecution is attempting to argue that their explanation is the best one. If alternative explanations are presented, the burden is to demonstrate that the prosecution's case is stronger and more likely than all other possibilities. Likewise, in history, explanations are proposed and supported by historical evidence. However, they are only accepted insofar as there is no contrary evidence. That there was a true, real human being Napoleon Bonaparte is not provable since we cannot see or talk with him. However, that he was real best explains the plethora of historical documentation and images.

IBE is also related to certain statistical theories, with the influence of Bayesian probability. However, not all supporters of IBE consider the *best* explanation to be the one that is most *likely* or *probable*. Bayesian probability allows for the subjectivity in inferential statistics and also provides evidence to decide which explanation is most likely, or in this framework, the *best*. While Bayesian probability is purely quantitative, IBE allows for a wide range of evidence, but as a principle it is concisely stated in extensions of the Bayesian theorem. For example, take the following:

$$P(H_1|E) = (P(E|H_1)/P(H_1))/(P(E|H_1)P(H_1) + P(E|H_2)P(H_2))$$

This equation expresses that the likelihood of Hypothesis 1 ($P(H_1|E)$) explaining the observed effect is equal to the likelihood that H_1 is a cause for observed E , $\left[\frac{P(E|H_1)}{P(H_1)} \right]$ divided by the likelihood of all, in this case 2, possible causes. Thus, as the likelihood of H_1 increases, the ratio also increases.

We can infer, then, a quantitative measure of how likely H_1 can be inferred from the effect. The equation will reveal the statistical evidence of which explanation is the best. If H_1 is more likely than H_2 , then we would have statistical evidence to support that H_1 is the most likely explanation, though not the only possible one. This Bayesian model allows statisticians to make a defined and quantitatively supported decision of which explanations are most likely. Some critics note that a Bayesian approach offers no rules for accepting a hypothesis but only offers statistical probability. IBE, at some point, does set a rule to accept the best explanation.

Critiques

IBE has been critiqued for its subjective epistemology. Karl Popper (1902–1994), a renowned philosopher, observed that IBE allows one to declare something as possibly or probably true. According to IBE, once an explanation has satisfied the scientist as the most likely to be true, it can be accepted, essentially, as true. However, critics push for a less subjective approach in science and require all hypotheses to be declared not as an expression of truth but rather as, simply, not yet refuted. Even though evidence may support one explanation more than other, the terminology of one being the *best* introduces a high level of subjectivity. Thus, IBE, though opening the possibility for an explanation to be refuted, allows scientists to declare their explanation as *best* (even determinately so) in the absence of what the scientist deems to be a better one. Additionally, IBE has been critiqued for being merely a type of inductive reasoning.

Conclusion

When seeking to explain phenomena, one infers possible causes. These explanations are then evaluated and the explanation that seems the best explanation, given all evidence, is accepted. Though one may never know a true cause for an effect with complete certainty, IBE maintains that the best explanation should be endorsed. Thus, the process of inferring explanations involves reasoning from phenomena to an explanation for it.

INFERENTIALISM

Inferentialism emerged as a theory of semantics to rival a once-dominant view that language is primarily representational. Representationalism, the long-standing view that linguistic signs represent objects in the world, was largely a common-sense understanding of language that dominated philosophy and science throughout much of Western history. Inferentialism, however, is a framework built around the notion that the meaning of a linguistic expression is found in its relationship to other expressions. Inferentialism proposes that (a) the act of being meaningful is ultimately an act of making connections between assertions (inferring) and (b) that these acts are governed by rules. The basis of inferentialism rests on the pragmatic notion that meaning is an act of doing. The primary way of doing meaning is through giving and asking for reasons, and therefore, it has often been referred to as a type of *linguistic rationalism*.

Representationalist theories of semantics underlie many of the philosophies in modernist thought, taking as a fundamental tenet that words, and other signs by extension, in some way *stand for* objects in the world. This representationalist

family of theories supposes that speakers use language to represent the world so that receptors of communication could thereby understand meaning contained in the signs. Inferentialism, by contrast, is a theory of meaning, suggesting that one interprets or *infers* meaning. This view has been applied to logic, philosophy, and semantics. Semantics, in this sense, is not solely about the word as such but rather how that word is used. Thus, inferentialism resonates well with American pragmatism. Many pragmatist thinkers point out that the focus on *what meaning is*, and *how things are meaningful*, should not be primarily understood at the word level but rather at the sentence level. That is, they proposed that semantics answers to pragmatics. Later thinkers have more directly developed this line of thinking to suggest that meaning is not represented by signs but rather is inferred from the use of signs.

While inferentialism may be used to theorize about semantics in general, it has special applications in logical and philosophical language (e.g., the logical connectors). The meaning of logical constants, for instance, can be understood as inferentially derived, thus allowing for forms of proof-theoretic semantics to emerge. In what follows, the history and fundamental tenets of inferentialism are considered; then applications to logical notation will be reviewed; and finally, a broader framework for semantics is presented.

Historical Foundations

Robert Brandom most recently and thoroughly codified the theory in his book, *Making It Explicit*, explaining that language makes explicit otherwise tacit relationships that are inferred. The term *inferentialism*, though coined by Brandom, can possibly be traced back to Immanuel Kant (1724–1804) and, more directly, to the language philosophers of the 20th century. Tracing the roots of inferentialism to Kant's transcendental idealism allows inferentialists to reject both pure rationalism and pure empiricism. At once, they deny knowledge is a priori, or that there is a world *out there* which we can know with no prior experience, while also denying that the mind is simply a blank slate. Specifically, in inferential approaches to epistemology, language is the focus of analysis. Knowledge is thought to reside apart from individual human experiences, and therefore

it is considered anti-empiricist. However, it is important to understand inferentialism not only as taking on the formal practices of reasoning, but that it is made explicit through language. Therefore, it does not follow the rationalist paradigm that knowledge is independent from human practice and is merely reasoned. Thus, the paradigm representative of an inferentialist epistemology can be traced at least as far back as Kant.

Another important step in the development of inferentialism was the influence of Ludwig Wittgenstein (1889–1951). In his later years, he proposed the notion that language was a kind of game. That is, the words were to be understood as functioning similarly to pieces in chess, and they had roles similar to the types of pieces. Hereby, meaning and language were linked, through the *use* of words and the *role* they play. Thus, language is rule-governed in the sense that it is used to play different games. Wittgenstein posited that there could be any number of language games, and he did not privilege any of them in his theory of language. While most of his foundational works were published posthumously from his lectures, his movement was toward viewing meaning as found in the use of a sign within a particular game, rather than in the sign itself. This marked a major shift in the way language was conceptualized.

Another proponent of this paradigm was Wilfrid Sellars (1912–1989), an American philosopher of the mind. Sellars, like Wittgenstein, saw semantics as studying the content of words in relation to their use. So, semantics was subjugated to rules of use rather than intrinsic content. Sellars noted that there was a type of rule that was, perhaps, more specifically responsible for meaning, namely, inferential rules, which was dubbed *the game of giving and asking for reasons*.

These theories focused on the pragmatic use of language, indicating that language does not merely *reference* things outside of a given context but rather is used in particular moments to *do* something in the context. Therefore, the meanings of words were not derived from their relationship to an object in the world but rather their use or performance on the world.

Brandom took a stance that the game of inferring is the primary game humans play with language, thus diverging from other postmodern followers of Wittgenstein. He proposed that *assertions* were the primary speech act of language. For

something to qualify as a linguistic practice, that is, giving and asking for reasons for these assertions, one was disposed to acknowledge the normative statuses of commitments and entitlements. Thus, the appeal to normative statuses of commitments and entitlements allows inferentialism to claim a sense of objectivity while maintaining those statuses as socially developed. In this way, inferentialism maintains that it is *linguistic rationalism* and also pragmatic in nature.

Key Concepts

Inferentialism can be seen as an expressive, ongoing process, or game, of being meaningful. One can look at language, then, as largely being concerned with linguistic moves that commit people to certain claims. Commitments and entitlements are key concepts to understanding inferentialism. When one makes a claim, or an assertion, there are always tacit, rational questions of *what that claim commits the speaker to* and *what is necessarily endorsed in order to be entitled to make the claim*. Thus, when one asserts, one may be liable to justify that assertion or give reason for it. So, when one commits to a claim, she opens up the possibility that another may demand justification for that claim. Any linguistic movement, then, not only adds commitments to assertions but also opens up the need to give reason for being entitled to that claim.

Commitment and entitlement compose the two major normative rules of the language game of inference. One must always *infer* to all those possible consequential commitments entailed by an original statement, and one must always *infer* the possible reasons for the statement to which they were entitled in the first place. The metaphor of gaming and scoring, then, is that when given an assertion, one keeps a score of possible future statements to which one could also be committed and possible previous statements that serve as entailments to a particular claim. The *game* is broadly a pragmatic theory, one of *language in use*. However, the pragmatic game can be stretched to become a semantic theory as well, that is concerned not only with use of sentences but also with content of words.

For instance, the *game of giving and asking for reasons*, as Brandom explains, hinges on the idea of keeping score of commitments and entitlements.

As one makes an assertion, the person is thereby committed to that concept. Also, the person ought to be committed to other assertions as well. Brandom uses the following example:

“The swatch is red.”

By using this statement, as a move in a game, one adds to the score that the speaker is thereby committed to the fact that the swatch is red. Additionally, the following statement ought also to be added to one’s score.

“The swatch is colored.”

The commitment to *red* thereby also commits one to *colored*. This could be called a *consequential commitment* because a commitment is made by virtue of being a consequence of an already explicit assertion. Each linguistic move must be treated as a commitment; otherwise, it has no real effect and thus is not rational. Herein, we can see how inferentialism receives its name. It is the relationship between concepts where meaning is inferred. The very rule that one who commits to “The swatch is red” is obligated to also commit to “The swatch is colored” demonstrates the inferential relationship between the linguistic sign and the conceptual content of the signs.

The key concepts of commitments and entitlements allow for inferentialism to be expressed as a form of linguistic rationalism by the likes of Brandom, to attempt to achieve a sense of perspectival objectivity. It also allows inferentialism to take up specific roles in logical and philosophical language. In logic and philosophy, there are often words that are considered constant in their meaning. Connectors, for example, have a very specific semantic role and a very restricted meaning. This allows for specificity in logical notation. Thus, applications of inferentialism in logic are considered.

Linguistic Rationalism

Inferentialism, at least in some varieties, seeks to ensure a particular type of objectivity, particularly through establishing commitments and entitlements as norm-governed acts. By *objectivity*, it should be clarified that what is at stake is not the truth of claims and whether they directly correspond to reality but rather whether the reasoning

through language is valid. This is the burden of the practitioner and is always open to further appraisal.

Objectivity, in the sense of matching the real world, is not possible and is not even a question for inferentialism. Indeed, when dealing with conceptual contents, one of the major critiques of inferentialism by representationalists, is that there seems to be no objective meaning. Some forms of inferentialism attempt to deal with this issue by proposing that objectivity exists from the view of a speaker. One makes claims that are rational and because they can be countered or reinforced. They also are objectives in that speaker's view. Because the rules for inference are normative, it is possible for people to speak to one another, viewing these practices as objective in nature, while they are in all actuality not objective. This type of linguistic rationalism seeks to secure the possibility of objectivity of thought, making the theory of inferentialism especially applicable to logic, philosophy, and even the sciences.

Beginning with the premise that any linguistic community is a rational linguistic community, Brandom claims that the following two statements differ significantly from one another:

- (1) The swatch is red.
- (2) It is assertable by me that the swatch is red.

Sentence (1) does not indicate *who* is committed or entitled to the claim, and thus it is possible to extend the claim to all rational beings, while Sentence (2), on the other hand, specifies *who* is committed and entitled to the claim. The two, though broadly similar, differ in the sense that they are incompatible under certain conditions. In both, the speaker is committed to the assertion; however, the entitlements are indeed different. The first requires investigation of the color of the swatch, whereas the second merely requires the investigation that the speaker has made the assertion. This difference, for Brandom, is the key to allowing for objectivity of thought. The *normative fine structure of rationality*, as he calls it, allows one to make objective assertions, following the normative reasoning of linguistic rationalism, despite social aspects of claim making and individual attitudes. Thus, the question of any assertion in relation to its propositional truth is whether the

practitioner has followed the normative rules of the assertion game.

In this game of giving and asking for reasons, there are three inferential roles that emerge. The first, *commitment preserving*, generalizes sentences that are used deductively. But deducing from previous assertions, it thereby preserves the commitments that are made. *Entitlement preserving* statements, generally, are inductive in nature. They amass support for a claim and thereby lend evidence for the speaker's commitment to an assertion. Finally, *incompatibility relationships* are inferential roles a sentence plays in commitment to incompatible claims. For example, "the car is red" also commits the speaker to "the car is not blue." These inferential roles are not the acts of inferring as such, but rather the marks on a *score-card* that are being checked off as commitments are made and consequential commitments are also marked off. Essentially, then, these are actions that occur to make everyday communication possible, as we tick off the *score* of others. We note the implication of the claim and the evidence laid for the claim. In this process, the normative rules of inferring from sentence to sentence allow us to understand the rational movements of the other.

Inferentialism, as can be seen, is a linguistic rationalist perspective on truth and relies on deductive reasoning between assertions that are made as well as those to which one is committed via the consequences of the assertion. Humans deduce meaning from these assertions. However, unlike rationalism proper, inferentialism does not begin with the premise that the world has an autonomous rationalist structure that humans can deduce outright. Inferentialism, rather, focuses on the innate, rational ability for humans to deduce, through reason, the relationships between premises, which may or may not correspond to the world-as-it-is.

Applications in Logic

Inferentialism has special applications to logic. Since the paradigm gives up the representational quality of signs in favor of an inferential quality, the logical vocabulary can be seen as a tool to make the implicit inferences between nonlogical commitments explicit. Particularly due to its claim of objectivity of mind, it can be applied to logic proper.

Specifically, inferentialism has implications for logical expressivism, that is, that logic is not reducible to mathematically inferential symbols but rather is intended to be used with real content.

Gottlob Frege (1848–1925), a German mathematician and one of the founders of modern logic, opened up the possibility to view logical connectors as governed by rules of proof, and therefore expressive in nature. Logic, in this view, then, is not simply a set of logical connectors but centers on the logical connectors as they make inferential commitments explicit. Logic, in this model, can be understood as the process by which the implicit relationships between content is explicitly stated.

Logical vocabulary, according to inferentialism, is derived from the use of inference in logical patterns. Inferentialism would hold the following, basic, logical test:

Abstract, logical example:

$$\begin{aligned} P \& Q &\rightarrow P \& Q \\ P \& Q &\rightarrow P \\ P \& Q &\rightarrow Q \end{aligned}$$

Specific, concrete example:

The sun is yellow. The sea is blue. The sun is yellow and the sea is blue.

The sun is yellow and the sea is blue. The sun is yellow.

The sun is yellow and the sea is blue. The sea is blue.

However, inferentialism holds to the meaning of $\&$ and $\rightarrow$ not because it is an autonomous system or because the world is explained through these logical connectors. Rather, inferentialism holds this test to be true because of the pattern of use that constitutes the meanings of the constants. The *conceptual content* of the logical signs can be inferred from their use. One may critique, as Arthur Prior, the logician, has, that this approach could allow for the existence of a logical contradiction and thus is a flawed approach. You cannot simply use a word “tonk” and infer meaning. The logic behind the statements would still be flawed. The simplified example that follows demonstrates that inferential rules alone do not constitute meaning.

Abstract, logical example:

$$\begin{aligned} P &\rightarrow P \text{ tonk } Q \\ P \text{ tonk } Q &\rightarrow Q \end{aligned}$$

Specific, concrete example:

The sun is yellow. The sun is yellow tonk the sea is blue.

The sun is yellow tonk the sea is blue. The sea is blue.

One cannot reason from the “sun is yellow” to “the sea is blue” outright. Even given the first example in which “tonk” connects the “sun is yellow” to “the sea is blue,” the inference could not be made that “the sea is blue,” because “tonk” fails to fix the meaning. “Tonk,” up until now, has no logical system in which to exist. Upon the second example, however, one could infer “tonk” as a logical connector (in this case with the semantic range of “and”) because it passes the logical test. Therefore, all logical connectors must be reasoned from their use. Critics propose that it is not possible to understand meaning as being conferred through normative patterns of use. However, that the tonk example exists does not necessitate that “tonk” is indeed a true logical connector in inferentialism. Logical constants are inferentially derived. Therefore, this is a semantic view of logic in which the language of logic abides by the concepts of use.

Inferentialism laid the foundation for *proof-theoretical semantics*, in which the reasoning between truths is ultimately an inferential activity. Proof-theory had long allowed for the logical deduction of truths from premises but only insofar as the logical syntax would allow. This is most clearly seen in mathematics in which formal proofs are treated as mathematical objects. The syntax allows for the proofs to undergo mathematical functions, following the rules of deduction. The study of the semantic component of logic was an innovative shift, leading away from resting epistemology on truths derived abstractly and syntactically but rather on the justifications of the claims derived semantically. We see this clearly in mathematics, as well, in which models of theories are the objects of study (not the proofs themselves). Thus, proof-theoretical semantics is an investigation into the knowing-how logical deduction is done.

Proof-theoretical semantics has allowed the inquiry into rules that govern logic. This has applications in mathematics and logic, as the inferential reasoning between concepts allows for the normalizability of proofs. Inferentialism is not concerned with the logical constants as representational figures but rather as the knowing-how to express already implicit relationships between assertions. As can be seen, inferentialism is a framework that is used in logic and philosophy. However, it has broader applications in semantics.

Semantic Theory

One variety of inferentialism is *conceptual role semantics*. Conceptual role semantics proposes that meaning can be seen as *causal*, based on individuals' reasoning or deducing through language from one assertion to another. This is different from some other varieties, which propose that meaning is *normative*, that is governed by rules of inference. In both types of theories, the act of inferring is primary, however, *how* that act occurs may differ. Conceptual role semantics, as a subset of inferentialism, helps to understand the realm of semantics. A related theory, *inferential role semantics*, arose in philosophy and is somewhat more restrictive to cognitive roles signs play in inference. The focus in these theories is what constitutes the meanings of linguistic expressions. Diverging from theories of semantics that assume a representational relationship between expressions and the world, in this paradigm the concern is with the role an expression plays in one's cognition. Thus, we can see that the relationship of interest is not the word and an object in the world, but rather the use of a word in linguistic expressions. This "use theory" of semantics generally falls under the domain of pragmatics, then. The meaning of words, or *semantic* meaning, is subject to their *pragmatic* use.

In linguistic theories, however, the distinction between semantics and pragmatics is an important analytical one. Here we may look at the relationship between the two, anchoring the discussion with considerations in syntax. Syntactic forms, such as declarative sentences, on the surface level, have no meaning independent from concepts and use. Thus, a sentence like the example introduced

earlier, "The swatch is red," is declarative in form. However, apart from the meaning of the concepts and the context of use, the sentence alone is meaningless. Likewise, once we consider the semantic domain, we will see that there are concepts involved. The concept of *swatch* and the concept of *red* are important to the meaning of the declarative sentence. However, there may be dozens of types of swatches and dozens of shades of red. Yet, we know we can talk about the concept of *swatchness* and the concept of *redness*. The commonality between all swatches and all reds is what we may call *conceptual contents* or *propositional* contents. Yet though there is some sort of content applied to the signs, the meaning is still unknown until we take into consideration that this declarative sentence is actually doing something. It is being used in a particular way, namely, to make an assertion. This is the pragmatic use of the expression. We can see, then, how linguistic expressions rely on syntactical forms, semantic conceptual contents, and pragmatic roles.

Inferentialism takes up this logic by claiming that the link to meaning is made in the transition between linguistic moves (some spoken, others unspoken but entailed). Semantics, in this way, will always fall short of explaining meaning unless the pragmatic use is considered. "The swatch is red," is, of course, only meaningful in relation to external information, or the relationship to other committed stances ("The swatch is colored") and from entitled stances (that one can critique the assertion to ask for reasons).

Within these *use theories* of language, it may be tempting to get caught in an endless cycle of meaning deference. That is, if a word, or any linguistic sign, has no intrinsic meaning and is arbitrary, then one may seek ad infinitum for a cause or explainer. However, inferentialism does not seek to define words in this manner but rather looks to the word's role in inference. Herein lies the significance of a word.

Conceptual role semantics is a theory of meaning but not a theory of truth. This is an important distinction because some philosophers have advocated for a *truth-conditional* view of semantics. In these theories, truth and meaning are tightly bound. The truth of a linguistic expression then

would depend on the truth of the parts, or the conditions, which would make the statement true. Conceptual role theories privilege the role an expression plays in a speaker's mind, and since no two speakers have an identical psychological state, the concept will be different, albeit slightly, perhaps. The concepts serve as a tool to allow inferences to be made and meaning is roughly found in the role the words play, not in the relationship to external conditions of truth. Meaning, both in semantics and in logic, is found in the inferential role signs play, not the representational or conditional truth of the sign itself.

Variations of Inferentialism

A variety of forms of inferentialism exist. Brandom's most widely articulated variety stands as a strong form, that is, the inferential use of language is primary among all potential uses, as noted earlier. This premise extends to any type of linguistic practice. Weaker or more moderate forms tend to apply this premise only to logical vocabulary, or that which is used to reason to and from set assertions. Michael Dummett and Dag Prawitz, also identified as inferentialists, have a much more restricted claim of language's inferential function in that it applies to logic specifically. Brandom's inferentialism expands upon these inferentialist approaches and thus is able to apply the "-ism" to an ongoing movement.

There are also varieties of inferentialism which employ inferences in the wide sense, that is, there are many types of inferences which may count in linguistic practices. Alternative views may restrict the inference merely to the operators in language. We begin to see, then, that inferentialism most clearly has its applications in logic, with some theoreticians extending its use beyond logic to the whole of language. However, there also is a variation on how inferentialist approaches relate to logic. Niel Tennant, for example, carries the Dummett and Prawitz trend to apply inferences within an intuitionistic logic, thereby reforming classical logic and taking an anti-realist position. This stands in contrast to Brandom's use of inference in classical approaches to logic. The variations, then, can be seen to exist on the types of inferences allowed and the application of the inferentialist approach to language in general or logic in particular.

Conclusion

Inferentialism, as we have seen, is a paradigm in the theory of meaning. It has historical roots in Kantian philosophies but was developed more thoroughly by logicians. In logic, inferentialism explicates the expressive function and inferential nature of logical connectors. Logical connections are not seen to exist autonomously but are rather ways of making inferences explicit. Mathematical and logical notation, for example, can be inferentially understood as expressing the relationship between content. This allows for proof-theoretical semantics to study the language and categories of logical notation, similar to model theory in mathematics. Thus, it is a semantic view of logic as opposed to a syntactic view. The formal connections are only meaningful if they are materially inferential as well. That is, formal rules of logic and rules of inference are not synonymous. Inferences must be materially good, that is, the content of the concepts must be inferentially related, thus deriving the formal rules of inference.

In the broader program of inferentialism, language as a whole, and even human cognition, is considered. In some varieties of inferentialist semantics, such as conceptual role semantics and inferential role semantics, the emphasis is placed on the role concepts play in human cognition and how meaning is inferentially derived from concepts. Other forms focus rather on the normative roles that concepts play in inference. In this later view, the rules of inference are seen to be normatively governed, that is, socially governed by way of giving and asking for reasons. The primary function of language, in this view, is to make assertions that commit the speaker to the conceptual content of the claim, and consequentially to other conceptual content as well. By making a commitment, however, one also is opening up the opportunity for the entitlement to that commitment to be questioned. Thus, every linguistic move shifts the scorecard, so to speak, in this language game.

INFORMATICS

Informatics is a loosely defined field of study generally focused on the creation, acquisition, transformation, and application of data. In practical use, there are meaningful distinctions between the academic field of informatics and the commercial implementation of related concepts. The term does not have a single unifying definition or agreed-upon framework the way some other fields may. Depending on the context and goals of a scholar or practitioner, the term may refer to work in the areas of data analysis (mathematics), algorithms (computer science), physical information exchange systems (electrical or network engineering), or even the public dissemination of data-driven knowledge (communication studies). Contemporary usage generally means any work labeled as informatics will be centrally focused on computer technology. Because the field is relatively new and is interpreted in different ways, this

entry begins with its etymological origins as a way of demonstrating the range of work reflected in the range of theories employed. Broader conceptual frameworks are addressed, followed by individual theories looking at technical and human aspects of the field.

Etymology

Because there is not a single, widely used definition of informatics, it is useful to know the history of the term as the evolution of the moniker reflects rapid changes in the field itself. Informatics is a relatively young field compared with other science, technology, engineering, and math (STEM) fields. Because of this, there are numerous connections to other STEM disciplines, but formal organization of work in the area is more recent and less rigorously organized.

The term *informatics*, in the English-speaking world, is sometimes assumed to be derived from the combination of “information” and Latin-derived “mathematics.” However, it is more likely to be a translational carryover from the German term *informatik* applied to the concept of data processing in the 1950s. Similar constructions follow such as the French *informatique*, Spanish *informatica*, or Russian *информатика* (informatika). Regardless of the specific language, the term seems to generally have a broad, inclusive definition regarding computing and data when in popular usage.

Conceptual Approaches to the Field

In more scholarly contexts, the varying definitions of informatics are overlapping but can be quite distinct depending on the source or application. Informatics Europe focuses primarily on the scholarly pursuit of the field and represents universities, research labs, and their partners based in Europe. Founded in 2005, the group closely identifies the field of informatics with areas often titled computer science, computer engineering, information technology, or information and communications technology. Conceptually, their usage may also refer to the study of human–computer interaction (HCI). Usage of the term across Europe is more likely to refer to these types of programs. Therefore, a European university is less likely to have a

department of informatics and a department of computer science, as they would appear redundant. In this view, informatics faculty or students may be developing specific theories of software development or designing new computer hardware in order to fill computational needs. This often requires strong collaborations with mathematics, physics, or chemistry.

In the United States, the term often has a slightly different connotation focusing more specifically on data and how they are created, stored, transmitted, or applied. For instance, some degree programs are interdisciplinary, combining mathematics, computer science, and other fields in which the work can be applied (e.g., biology, political science, journalism) rather than a stand-alone department. In other cases, institutions have departments or schools of information containing multiple degrees or programs of study each focusing on different aspects of the overall concept of informatics. Scholarly fields that focus on creating technologies and tools are, generally speaking, older and more established than the more recent higher learning approaches to studying data itself. Consequently, there are many more academic programs that identify as computer science or electrical engineering in the United States than there are those that refer to themselves as informatics. A U.S. American university is more likely to have both a department of informatics (or information science) and a department of computer science, as they would occupy different spaces in the overall technology landscape of the organization. In this view, informatics faculty or students may be acquiring and investigating data as a focus, only employing software and computing systems as a secondary need to fill their primary mission.

Schools of information in American universities may also conceptualize informatics more as the systematic study of how to organize, archive, and make accessible to the public knowledge derived from data. For instance, the term *data science* refers to many of the same efforts and conceptual work as informatics but more explicitly focuses on data itself rather than the systems that make use of data. This might be conceptualized as a field directly related to informatics or as a subdomain of informatics itself, depending on the focus and design of the institution. For example, computer science may develop techniques for natural

language processing, while informatics or data sciences seek to develop frameworks for creating and mining large corpuses of human utterances. Similarly, an informatics approach to artificial intelligence might focus on the large data sets necessary for machine learning but not on developing the models themselves.

There is a global trend across organizations that train professional librarians to either align with informatics and similar programs or outright combine them into a single approach to information management in a field sometimes referred to as *library and information science*. The American Library Association aims in its mission to promote library and information services. The Chinese government combined programs in their national attempt to promote automation technology in libraries into a single digital library and information systems approach. Support of these processes and public services requires supporting or relying on work common in the field of informatics.

In more commercial or applied contexts, the term *informatics* tends to be strongly associated with collecting large amounts of data from individuals and groups in order to identify trends, make predictions, and develop products or services. Though the utility of analyzing data is not new, since the start of the 21st century, analytical analysis of information has rapidly become a fundamental component of the business, nonprofit, and government/social service sectors. Of particular note, marketing and advertising industries have seen heavy reliance on developing methods of collecting detailed information not just on large audiences but also on individual people. Data about their demographics, past experiences, and current activities are of potential use in making predictions about their future activity. This is valuable to a business marketing a product or a social service entity attempting to change the activities of people in the public.

Health care is an area of particular importance regarding analytics because there are a number of stakeholders and potential uses for collected data. For example, a hospital may track multiple factors about each patient receiving treatment. These data can be analyzed to evaluate hospital and doctor performance while seeking to improve outcomes or evaluate distribution of limited resources. However, the same data might be useful to

companies developing and selling medications or health insurance. Governments and related social organizations might use this data to support public health campaigns or design legislation. In turn, individuals may be motivated to use digital tools and wearables to improve their own health, such as popular health and activity trackers. Each of these vectors is intertwined in complex ways that can support business and health outcomes, but only if there are ways of collecting, processing, and making use of the data. Informatics plays a key role in these kinds of endeavors whether it takes the form of designing health-measuring electronics, analyzing data, or supporting recommendations for health strategies.

Theoretical Constructions

Because informatics is a new field relative to many of the ones it draws from or connects to, many of the theoretical constructions used in scholarship or practice often come from other places. The term *debtor field* refers to an area of study that primarily draws from others in order to execute its work. If considered from the viewpoint that informatics is essentially another term for computer science, network engineering, or information technology, then most of the theory employed naturally comes from those constituent fields. Alternatively, if informatics is viewed as its own relatively new field that looks at information science but connects to other STEM fields, much of the theory used may be labeled as coming from other fields, and informatics itself may seem theoretically sparse.

In any case, the theoretical concepts and approaches used in informatics can be most easily categorized based on the goal of the work. The fundamental purpose of a theory is to explain. In informatics, theories generally focus on large-scale, epistemological aspects of finding and using data (conceptual frameworks) or on narrowly tailored approaches to understanding how a specific problem or question is addressed (theories).

Conceptual Frameworks

Systems theory is an approach to understanding people and technologies by treating them as systems or machines. Humans are generally capable

of considering how a system works through chronological or cause-and-effect relationships. Systems have interconnected parts that are dependent on one another to complete a large task that no single part could complete on its own. Combustion engines, desktop computers, and factories are examples of systems. The systems approach takes a complex environment of interacting components and studies it by using many of the same techniques a mechanic would use on an engine or an engineer would use in a factory. Looking for the order in which events occur, what effects they cause, and how small changes can significantly affect system outcomes allows a researcher or practitioner to identify which technologies or people might be changed in order to produce a desired outcome. Systems theory can be used to study human-made technologies, human communication, or even naturally occurring phenomena.

Related to systems theory is another framework called *cybernetics*. Rather than considering a single, self-contained system, this approach assesses the interaction and influence of intelligent systems on one another. The theory assumes that a system is intelligent insofar as it has a goal of some type and reacts to outside stimuli to continue achieving that goal. Depending on the specific application of the theory, it can be used to study how systems handle information processing, feedback, and control in addition to how they can regulate each other or respond to interruption. This framework has been applied to a wide range of technologies and human communication.

Humans typically have definable purposes for using technology. *Uses and gratifications theory* has been used in a number of scholarly fields since the 1940s. Originally focused on understanding why people select and use the communication media available to them, it has been significantly expanded and adapted since that time. This approach is no longer considered as strong as others by a number of scholars, but the essential concept that people do things to satisfy their needs has underpinned a number of other important theories with regard to humans using technology. A related theory, *activity theory*, is a more socio-cultural approach to understanding what motivates people and how they relate to the objects and processes necessary to accomplish their goals.

Theories

Because the field of informatics does not have a clear boundary and is instead still developing and overlaps with others, there is a broad range of theories applicable to the field, reflecting the wide array of questions it attempts to answer. A brief selection of useful theories is presented here.

From the perspective of computer science, mathematically driven theories are particularly useful. *Analytic number theory*, broadly conceived, is a mathematics theory that compares the outcome of a function with its approximation. A more specific use of this in computer science is in applying mathematical functions reflecting the design of software to make predictions about how complex specific algorithms are in order to determine their efficiency and optimal use. In computer science and informatics, the most common use of this approach is referred to as *Big O notation*. *Graph theory* looks at relationships between paired items in a network of related components. It provides mechanisms for analyzing and optimizing the connections in a system to better find relationships between data points. For example, software to generate driving directions might treat cities as nodes paired (related to each other) by the roads that connect them. Routing equipment uses graphs to compute best paths for data to take through a network.

In many cases, it is preferable to have a general device that can solve many problems rather than a specific machine for each problem. Alan Turing's work in the early days of computing contributed immensely toward this end. A *Turing machine* is a device that solves a range of generalized problems based on specific input and rules. Essentially, theories around Turing machines have to do with calculating whether a given machine will be able to solve a particular problem within specific constraints. The ability to mathematically calculate whether a system can solve a problem is incredibly valuable in designing both hardware and software. Computer scientists, computer engineers, and mathematicians all work together in this area, designing technologies capable of reliably solving problems and directly or indirectly proving they will work rather than investing in a system that will ultimately fail.

Moving away from the purely mathematical and toward the interaction of machines and people, a number of theories and approaches are useful. Originally drawing from psychology, a *theory of affordances* describes qualities of an object that suggest how the object should be used by people. The idea is that designing an object so that it is obvious how it should be used is more efficient and intuitive than a more abstract object that requires labels or instructions. Examples such as a hole the same shape as a peg, a knob that only turns in one direction, or lights meaning something is turned on make the interface for a system easier without training. Different versions of this approach disagree over whether the affordances should or should not be culturally sensitive or whether perceived affordances are the same as objectively true ones. In any case, the theory helps explain how objects should be designed so that people can make most effective use of them.

In the 1990s, *information-foraging theory* was developed by treating how animals seek out food as analogous to how humans seek out information. It proposes that people make rational decisions based on the perceived value of an information source relative to the difficulty in using it. For instance, a website that contains a large amount of information in an easily accessible format is a high-value source relative to a book that contains less information and lacks the ability to readily locate specific topics. One could use this theory to predict the success of a source such as Wikipedia over traditional print encyclopedias. Information foraging is conceptually related to the psychologically based communication concept known as *social exchange theory*, which posits that people manage their relationships by evaluating the return they receive for an investment of time and information disclosure. Information-foraging theory is useful for predicting the types of sources people will use and how best to present data for particular audiences based on their abilities and motivations.

INFORMATION THEORY

Information theory is the name given to the study of signaling and communication as an abstract field, separated both from the physical problems of building communication systems and from the meaning of the information communicated. The theory is principally concerned with operationally well-defined ways of quantifying uncertainty: Its focus is upon the probability of potential signals being sent. The fundamental unit of this quantification is a *bit*, which represents complete uncertainty regarding which out of two possibilities is the case. The Shannon information measure generalizes this to an arbitrary number of possibilities and to varying degrees of certainty.

The two most important applications of information theory are to data compression, the efficient and accurate storage of data, and to error correction, the efficient transmission of data

without errors introduced by noise. Information theory underpins almost all modern information processing and communication technology. The following sections explain the relationship between information and uncertainty, in general and in situations where a correlation exists between different systems. Next, the operational properties of the Shannon information measure are described, and the entry concludes with a discussion of the relationship between information theory and extant notions of computational complexity.

Information and Uncertainty

The Shannon information measure was introduced by Claude Shannon in 1948 as a means of quantifying the uncertainty of a source of signals but has been generalized to uncertainty about any general state of affairs.

Communication systems involve encoding messages into a standardized set of signals, which are transmitted from source to receiver, and then reconstructing the sent message from the received sequence of signals. Simple examples of this include Morse code and semaphore. By focusing on the abstract properties of such coding schemes, Shannon was able to identify key properties of information common to all such systems.

Each possible message has a particular probability of occurring for a given signal source. The Shannon information of the signal source is given by the expectation value of the logarithm of these probabilities. It has a simple operational interpretation: To find out which message was sent by asking a sequence of yes–no questions, the best possible strategy will, on average, require a number of questions equal to the Shannon information. This strategy is equivalent to coding the message as a sequence of ones and zeroes, which represent the yes or no answers to the optimal sequence of questions. The ones and zeroes of the coding scheme are binary digits, or bits, and the Shannon information measure represents the average number of bits required to encode messages from the signal source.

The measure has a number of natural properties for a measure of uncertainty:

1. If the message is known, the measure is zero: there is no uncertainty.
2. For a given number of messages, the measure is a maximum when all signals are equally probable. The greatest degree of uncertainty is when no possibility is any more likely than any other.
3. As the number of potential messages increases, this maximum increases. Adding more possibilities increases uncertainty.

It might seem counterintuitive to have an information measure that increases as uncertainty increases. Normally, information might be seen as the opposite of uncertainty. This contradiction is typically resolved by describing uncertainty as quantifying the lack of knowledge about which message is sent while describing information as quantifying the resulting gain in knowledge when the message is received.

The Shannon measure has a further property that uniquely defines it: If a given possibility can be divided into more fine-grained possibilities, the uncertainty over all fine-grained possibilities is equal to the uncertainty of the coarse-grained original possibilities, plus the average of the remaining uncertainty over the additional fine-grained possibilities. Broadly, this corresponds to the idea that it does not matter the order in which fine-grained information is acquired: If you are uncertain which playing card is drawn from a deck of cards, your uncertainty should not depend on whether first you are told which suit it is and then told the number or whether you are simply shown the card straight away.

Acquisition of new knowledge will, on average, reduce uncertainty. However, uncertainty is not necessarily reduced in all cases of acquiring knowledge. The measure does not quantify how correct someone is. Suppose someone is 95% sure that their keys are in their pocket, but equally uncertain of a great many other places the keys might be if not. They are reasonably certain, but not completely certain, where their keys are. Putting their hand into their pocket can reduce the uncertainty to

zero, if the keys are there, but will greatly increase their uncertainty if they do not find their keys.

Information Between Correlated Systems

An important part of information theory is quantifying uncertainty in situations where there is a correlation between two different systems. This involves the joint, conditional, and mutual information.

The joint information about the two systems is simply the uncertainty over all pairs of possibilities for the combined system. The conditional information for one system is the difference between the joint information and the uncertainty for the second system alone. It represents how much uncertainty remains about the first system, once all uncertainty for the second system has been removed. In the case of systems where there are no correlations, the conditional information is equal to the initial uncertainty about the first system. If there are correlations, the conditional information is less than this: Finding out about the state of a correlated system also gives knowledge about the state of the first system.

It should be noted, however that like the uncertainty measure in general, this reduction holds only on average. It may be the case that finding specific data about the second system can leave someone less certain about the state of the first system than they had been beforehand, for example, in the case where the second system is the location of someone's keys and the first system is the place they are going to eat dinner. For perfectly correlated systems, the conditional information is zero: Finding out the state of one system will leave nothing left to know about the state of the other system.

The mutual information is the difference between the sum of the individual uncertainties and the joint information: It quantifies how much information is held in the correlation between the two systems. For uncorrelated systems, it is zero. For perfectly correlated systems, it is equal to the joint information itself.

Operational Treatment of Information

The Shannon information measure, while having properties that seem to capture many intuitive

aspects of information and uncertainty, derives its principal importance from its operational properties. It provides a measure of the ability to efficiently store and transmit information through data compression and error correction.

Data compression refers to the need to encode messages in the smallest number of possible signal states, such as the dashes and dots of Morse code or the ones and zeroes of binary digits. Given a fixed set of possible messages, and a finite number of possible signal states to be used to send the messages, what is the most efficient means of encoding the messages in the signal states?

The noiseless coding theorem shows that the average number of signal states used per message cannot be less than the Shannon information measure of the probabilities of the messages. This theorem applies equally to storing information, such as in the registers on a computer's hard drive, as it does to sending signals over transmission lines. The most efficient schemes for compressing data files in video, audio, or document formats will approach the Shannon measure for how much space they must occupy on a computer.

To achieve the Shannon limit for data compression, the coding scheme must assign a probability to each message, then assign a unique sequence of signal states to that message, in such a way that the more probable messages have the shortest sequences of signal states and the least probable messages have the longest sequences. So, in the English language, the letter E, which is the most frequently occurring, would be represented by a very short code, while the letter Q would tend to be represented by a longer code.

Finding optimal data compression schemes is not straightforward. Although Q is not a frequent occurrence in English, it occurs far more frequently in conjunction with U than in conjunction with X. Truly efficient data compression schemes look for patterns or sequences that are more probable than others. At the extreme, messages might be more efficiently compressed at the level of whole words or even sentences or paragraphs, than individual letters, but practical problems with even all the possibilities, and assigning probabilities to them, rapidly outweigh any gains that might be achieved by such schemes.

The noiseless coding theorem does not take into account the possibility of errors occurring.

Data that are stored or transmitted might be corrupted or distorted by noise. The noisy coding theorem concerns the rate at which messages can be transmitted, without error, along a communication channel which has noise. In a communication channel which has no noise, the signal state transmitted will be the signal state received; there will be a perfect correlation between transmitter and receiver. When there is noise and interference in the channel, a given signal state will have some probability of being corrupted to a different signal state or lost altogether. The correlation between transmitter and receiver will be imperfect. Mutual information measures the correlation between the transmitted and received states.

Error correction codes involve adding extra length to the sequences of signal states to protect the message against this. The simplest example of an error correction code would be one in which a zero is represented by a sequence of three zeroes and a one is represented by a sequence of three ones. If a single one of the transmitted bits is affected by noise and changed to a different value, the remaining two bits still faithfully represent the signal. The receiver can still tell which signal was originally sent by taking the majority. To lose the message, two of the transmitted bits would have to be affected by noise, and this is less likely to happen.

Increasing the length of the signals by using an error correction code will reduce the probability that the wrong message is decoded by the receiver, at the cost of needing more signal states to transmit the same amount of information. The rate of signal transmission measures the average number of signal states transmitted per signal state used in the error correction code. The noisy coding theorem shows that a transmission channel subject to noise has a maximum rate at which signals can be transmitted without error, called the *channel capacity*.

This is given by the mutual information between the signal states and the received states, for an optimal choice of signal probabilities, with respect to the noise in the channel. The information theoretic quantification of the degree of correlation, between transmitted and received signal states, is therefore also the operational quantification of the minimum rate at which the signal states must be lengthened to correct for errors in the messages.

Further Developments

The Shannon information measure is intimately linked to notions of computational complexity. The compressibility of a signal source can be recast in terms of what a computer program can achieve as the encoding and decoding device. Kolmogorov complexity theory relates Shannon information measures to the length of computer programs and the abstract idea of computers as universal Turing machines. In many respects, the theory of computers as Turing machines reflects the same concerns as information theory, separating computer science both from the physical problems of building computers and from the significance of the computations performed.

The operational connection of the information measures to data compression and error correction is clearest when a single signal source transmits down a single line to a single receiver. The quantification of information becomes more complex in more complex scenarios, involving multiple parties, where security, privacy, and authentication are problematical.

The uniqueness of the Shannon information measure depends upon the importance attached to the average cost, in terms of bits, of transmitting messages. However, optimizing a resource cost by an averaging process is not always desirable, particularly in situations where there is a long tail of highly improbable outcomes that may nevertheless have a significant impact on the average. Alternative strategies might involve disregarding very low probability events or might involve adding extra weight to such events to provide protection against catastrophic failures. A family of information measures exists, the Renyi information measures, which include the Shannon information measure as a special case, and generalize the methods of information theory to account for alternative optimization strategies.

The separation of information theory from the physical problems of constructing processing and communication devices has been challenged by quantum theory. Information processing and communication tasks performed by quantum devices can, in some cases, appear to exceed the resource bounds set by information theory. This has led to the development of quantum information theory as a new field of research. Analogues

of the data compression and error correction theorems lead to a quantum measure of information, which contains the Shannon measure as a special case.

Information theory also seems to have a close parallel to statistical theories of thermal physics. The Shannon information measure has the same mathematical form as the Gibbs entropy, and it is commonplace to find physics textbooks referring to thermodynamic entropy as a measure of uncertainty or ignorance.

INFORMATION THEORY, HISTORICAL BACKGROUND

Quantitative information represents objective properties in the natural and social worlds in the form of quantities, numbers, statistics, and frequencies. As opposed to qualitative information, which is concerned with human experience, meaning and motives, quantitative information is the product of mathematical models and hypotheses. Quantitative information begins with empirical observation so as to mathematically express casual and correlative relationships. Assuming that the world is rational and discoverable, quantitative researchers operationalize and isolate concepts by controlling for extraneous influences, then use statistical, mathematical, and computational techniques to analyze numerical data collected from a representative sample to draw lawful

generalizations about a larger population. Following the work of French philosopher Auguste Comte (1798–1857), quantitative information is used to develop testable theories about the products, patterns, and processes of empirical phenomena in the social, behavioral, mathematical, and natural sciences.

This entry first describes the cultural transition from orality to literacy that makes quantitative information possible by abstracting words and numbers from immediate experience and separating logic from the essence of sociality. Second, it discusses Euclidean geometry as a model for grounding the natural and social sciences in quantitative information. Third, it outlines the efforts of Francis Bacon (1561–1626), Galileo Galilei (1564–1642), René Descartes (1596–1650), Isaac Newton (1643–1727), and Comte (1798–1857) not only to legitimate quantitative methods but also to create a modern mentality centered on quantitative information.

Contemporary understandings of quantitative information concern not only the nature and scope of quantitative information and its ability to represent the empirical world but also the capacities and limitations of quantitative methods and their ability to locate and capture information about the social world. Quantitative information combines the notions of measurement and counting, done every day in the real world, as well as the model of functions that grounds Newtonian mechanics and, more recently, statistical data analysis procedures developed in the 19th century.

The dominance of Newtonian mechanics since the 18th century, and at least in colloquial discourse since Einstein in the 20th, promotes a confidence in the explanatory power of quantitative information that grounds the modern world. The spirit of quantitative information presupposes that everything in the empirical world can be measured, and it is the goal and responsibility of modern science to measure it. In the 19th century, the purview of quantitative information was extended beyond necessarily causal phenomena held together by deterministic laws, as in Aristotle's physics, to contingent events associated by probabilistic relationships, traditionally the province of rhetoric.

Together the work of Euclid in the 3rd century B.C.E, Bacon, Galileo, Descartes, and Newton in

the 17th century, and Comte in the 19th century, among many others, have used quantitative information to synthesize ancient and medieval worldviews into a modern world. Descartes's tree of knowledge rooted in metaphysics and Comte's pyramid of knowledge based in mathematics have both legitimated the use of quantitative information as a way to understand the world, and became the backbone of 19th-century science, and the impetus for modern society that revolves around progress, efficiency, and individual autonomy.

From the compatibility with human experience of Euclid's geometry, Bacon's method, Galileo's cosmology, Descartes's doubt, and Newton's mechanics emerged a new modern mentality with quantitative information at the fore. Before explicating the work of Euclid, Bacon, Galileo, Descartes, Newton, and Comte and its influence on the development of quantitative information, let us first describe the cultural conditions that made quantitative information possible in the evolution of words and numbers from primary orality to literacy.

From Orality to Literacy

In *The Presence of the Word* (1967) and *Orality and Literacy* (1982), historian and philosopher Walter J. Ong argues that the consciousness of people with no knowledge of writing differs in fundamental ways from that of literate people and those with knowledge of electronic media. The oral consciousness always lives in the present and commands an immediate audience. The spoken word only makes sense when there is someone present with whom to speak. Oral cultures revolve around narratives, such as Homer's *Iliad* and *Odyssey*, that celebrate and perpetuate the culture's values. In orality, story is history. The storyteller embodies the story and cannot detach himself from it. There are no written records, so culture is embodied as the personal and subjective and performed for others in a repetitive and incremental way. The consciousness of literacy, on the other hand, abstracts words from experience and outsources memory to written records. The writer's audience is always a fiction that emerges from a linear understanding of past, present, and future that privileges objectivity. From this perspective,

the technology of writing alienates the self, exteriorizes thought, and restructures consciousness.

The spoken word in oral cultures differs from the written word in literate cultures in several ways. First, the spoken word is additive rather than subordinative. Whereas the written word obeys strict syntactical and grammatical rules, the spoken word is linear, adding one event to another to aid memory, as in the opening lines of the Book of Genesis in the Douay-Rheims Bible: "In the beginning God created heaven, and earth. And the earth was void and empty, and darkness was upon the face of the deep; and the spirit of God moved over the waters. And God said: Be light made. And light was made."

Second, the spoken word is aggregative rather than analytic. The opening stanzas of the Babylonian epic of Gilgamesh read, "Whose name, from the day of his birth, was called 'Gilgamesh'? Two-thirds of him is god, one-third of him is human . . . beautiful, handsomest of men . . . perfect." These adjectives that pepper speech in oral cultures would be cumbersome and flowery as written sentences. Third, the spoken word is redundant and conservative. Redundancy in speech makes it easier for the rhetor to remember and the audience to follow, as in the African epic of *Sundiata*, which reads, "King of Nyani, King of Nyani, / (Mmm) / Will you ever rise? / King of Nyani, King of Nyani, / (Mmm) / Will you ever rise?" The conservative nature of the spoken word allows oral cultures to pass on their cultural values from generation to generation without written records.

Fourth, the spoken word in orality is close to the human lifeworld and agonistically toned. There are no abstract concepts in orality. The violent imagery of the spoken word in antiquity, as in the climactic scene in Book 22 of the *Odyssey* when Odysseus returns to Ithaca to face the suitors for his wife Penelope, gives meaning to the struggle for survival in the ancient world. Finally, the spoken word is homeostatic and empathetic rather than objectively distanced. Spoken words in oral cultures correspond to one meaning. Without written records, the layers of meaning present in literate cultures are unnecessary.

For Ong, writing is an artificial technology that transforms human consciousness. Writing disconnects words from the existential present. Words, numbers, and their manifestation in the

form of quantitative information become events independent of time and space. Writing separates individuals from the group in space, thought, and work. Letters and numbers are extensions of the sense of touch that fragment and detribalize man. The advent of print permitted replicability and reproduction of abstract units that created a sense of the abstract infinite, which distracts man from his fundamental finitude. The invention of writing changed the social fabric of the West by compartmentalizing time into measurable fractions. Events in time no longer created their own time and space but were contained within time and space. Preliterate cultures experience time; they do not measure it.

Also, existential settings infuse words with meaning in ways that dictionaries cannot. In oral cultures, auditory utterance shapes and determines the cognitive thought processes of the speaker and audience. All speech is shaped by an anticipated response. The technology of writing separates words from their author by separating logic from rhetoric, the knower from the known, and sight from sound. The written word is voiceless and cannot be directly challenged or contested like oral speech. This detachment occurs in oral cultures when the speaker is considered only the channel, not the source of oral speech, as in oracles or religious rituals. Critiques of the effects of technology on culture, most notably by Plato in the *Republic*, were themselves made possible by the effects of writing on mental processes.

Ong argues that writing is unresponsive, artificial, and manufactured. Writing weakens the mind and destroys memory. The distance between a text and its author sharpens the analytical capacity of individual words and numbers. Printing spawns the need for listing and indexing that further detaches and abstracts the words of a text from their situational and linguistic context. The tangibility and visual nature of a printed text, as opposed to the fleeting and existentially present spoken word, promotes knowledge as an illustration in space, independent of time and source. According to Ong, the printed word allows for an objectification of human consciousness that, in turn, fosters interiority and privacy that did not exist in action-oriented oral cultures.

The interaction of writing and orality, and the impact of residual orality, is manifested clearly in

the development of rhetoric, the art of oral address for persuasion. Because rhetoric cannot be detached from the human lifeworld, rhetoric characterizes the entire human experience, not just public speech. Rhetoric is not only a means of persuasion but also the means of identity affirmation. The emphasis on rhetoric as the essence of sociality demonstrates its close connection to the human lifeworld. For Ong, quantitative information has no meaning outside of a shared social context in the rhetorical arena of lived experience.

Euclidean Geometry

The evolution of the word from orality to literacy in the ancient Greek world made possible the evolution of geometry from a practical and economical means of measurement, to a deductive science that sought knowledge for its own sake. Euclid's axiomatic-deductive geometry is representative of this trend in the 3rd century B.C.E. and continues to influence the infrastructural foundations of quantitative information in both the natural and social sciences.

Euclid outlines his approach to geometry in the *Elements*, written in Alexandria around 300 B.C.E. In Euclidean geometry, axioms are presented as self-evident descriptors of natural reality. From those axioms, deductive logical inferences are used to prove theorems using only a ruler and a compass. Notwithstanding the development of non-Euclidean geometry and Einstein's relativity developed in the 19th and 20th centuries, Euclid's *Elements* has formed the foundation for quantitative information in the natural and social sciences. The *Elements* contains a series of axiomatic postulates, from which theoremetric propositions are deduced through mathematical proofs.

The contents of the book range from the postulate of plane geometry, including geometric algebra and the properties of circles, triangles, and polygons, to ratios and proportions, including magnitudes, divisibility, series, and sequences, to spatial geometry, including pyramids, perpendicularity, and parallelism. In the *Elements*, Euclid first defines a point—that which has no part—and a line—a length without breadth—then defines an angle as the inclination of two straight lines, and a circle as a plane figure consisting of all points that have a fixed distance from a given center.

These definitions in Euclidean geometry apply to flat space, where the distance between two points in two or three dimensions can be calculated by an axiomatic-deductive formula. For instance, when drawing on a flat piece of paper, it is easy to observe that the shortest distance between two points is one unique straight line, that the sum of the angles in any triangle is 180° , or that through a point not on a line there is no more than one line parallel to the line.

The oldest extant treatise of axiomatic-deductive mathematics, the *Elements* was among the first texts to be typeset after the invention of the printing press, second only to the Gutenberg Bible in number of editions printed. Until the second half of the 19th century, geometry was synonymous with the Euclidean geometry taught in secondary schools. Euclidean geometry allowed one to apply theorems in diverse situations by generalizing centrifugally from a few known facts. Although other non-Euclidean geometries developed in the 19th and 20th centuries have added to Euclid's understanding of finite space, Euclidean geometry remains the most compatible conception of space with how human beings experience the world. This emphasis on proof through insight rather than memorization infused quantitative information with not only descriptive but also generative explanatory power.

The Scientific Revolution as the Spirit of Quantitative Information

With the publication of *On the Revolutions of the Heavenly Spheres* in 1543, Polish astronomer Nicolas Copernicus sparked a scientific revolution that would culminate with Newton's *Mathematical Principles of Natural Philosophy* in 1687. In his book, Copernicus laid out his heliocentric vision of the universe with the sun, not the earth, at the center of the solar system. This view of the universe was directly at odds with the Ptolemaic cosmology based on Aristotelian mechanics, with the earth at the center of the solar system surrounded by the other three basic elements—air, water, and fire—revolving in concentric circles. Copernicus's heliocentric cosmology took the place of Ptolemy's geometric cosmology but provided no replacement for Aristotle's mechanics. Without this replacement, the Copernican system

was counterintuitive. If the earth is spinning on its axis and revolving around the sun, why does it appear at rest to the casual observer?

Italian philosopher, astronomer, and mathematician Galileo Galilei induced an answer from his experiments with balls rolling on incline planes. In his *Discourses and Mathematical Demonstrations Relating to Two New Sciences* (1638), Galileo argued that Aristotle was wrong to believe that unnatural motion required a proximate cause. Instead, an object in motion, like the earth, will tend to stay in motion through inertia. Because everything on earth is moving contemporaneously, the movement is imperceptible to the casual observer. After French philosopher and mathematician Rene Descartes extended Galileo's principle to motion in straight lines, Isaac Newton restated it as his first law of motion in the *Principia*.

Galileo's observations using the telescope led him to accept in theory the Copernican system. However, Copernicus still adhered to some Platonic ideals that left many unanswered questions in his heliocentric vision. German mathematician and astronomer Johannes Kepler (1571–1630) devoted his career to answering these questions. Kepler proposed that the orbits of the planets were not circles, as Plato argued, but ellipses around the sun that could be calculated as a function of the planet's distance from the sun. Newton's universal law of gravitation and postulates on force, mass, and motion were a synthesis of the work of Copernicus, Descartes, Galileo, and Kepler, and at last provided the replacement for Aristotle's mechanics within Copernican cosmology.

Galileo's Defense of Quantitative Information

The work of Galileo legitimated the use of observation, measurement, and experiment now synonymous with scientific method and quantitative information. In *The Assayer* (1623), Galileo argued that the language of mathematics can explain the growth of the smallest plant and the workings of the entire cosmos with the same precision. His words in *The Assayer* are worth quoting at length: "Philosophy [i.e., physics] is written in this grand book—I mean the universe—which stands continually open to our gaze, but it cannot be understood unless one first learns to

comprehend the language and interpret the characters in which it is written. It is written in the language of mathematics, and its characters are triangles, circles, and other geometrical figures, without which it is humanly impossible to understand a single word of it; without these, one is wandering around in a dark labyrinth."

In 1609 in Padua, Galileo began observing the heavens with his 20-powered spyglass telescope. He observed that the surface of the moon was rough and cratered, not smooth and even, that four moons revolve around Jupiter, and that many more stars exist than are visible by the naked eye on Earth. Galileo later discovered the anomalous appearance of the planet Saturn, and the phases of the planet Venus. The discovery of craters on the moon contradicted Aristotle's cosmology, in which the imperfect earth existed below the perfect Heavens. The discovery of the moons orbiting Jupiter showed that the earth could not be the only center of motion in the universe. The discovery of the phases of Venus showed that Venus revolves around the Sun and led to Galileo's conversion from Aristotelian to Copernican cosmology, in which the sun, not the earth, is the center of the universe.

Aristotelian objectors to Galileo argued that science concerns universal laws, not particular observations, and that a science of particulars grounded in observation, measurement, and experiment can achieve no knowledge of the universal and unobservable laws of physics. Galileo responded to Aristotelians who argued that measurement and observation tell us nothing about the essence of natural phenomena by arguing that God set the world in motion through geometrical laws, and that these laws are knowable through observational measurement. For instance, the imperfections on the surface of the moon visible through Galileo's telescope are incompatible with the Aristotelian law that all planetary bodies are perfectly spherical.

Galileo's elaboration on Aristotle's idea of induction also has implications for quantitative information. In the *Posterior Analytics* (350 B.C.E.), Aristotle described induction as a cognitive process whereby one argues from a particular to a universal to arrive at the first principles of science. Galileo developed Aristotle's idea of induction as a justification for grounding scientific

knowledge in observation. One proves the truth of the universal laws that ground empirical sciences through inferences made from many observations. Galileo's defense of quantitative information from Aristotelian ontologists legitimated the use of quantitative methods in natural philosophy and astronomy.

Quantitative Information and the Modern World

Francis Bacon

Francis Bacon's faith in the perfection of the scientific method and experience as the sole source of knowledge has guided the spirit of quantitative information. Bacon's *New Organon* (1620) was a comprehensive re-legitimation of natural science using natural philosophy to reform scientific method. Bacon sought to create a new method of inducing universal laws from particular observations. Bacon's "tables of discovery" provided new ways to process and make sense of particular human experiences. By categorizing particular experiences using these tables, Bacon argued that one could induce physical causes and metaphysical essences of phenomena.

In the *New Organon*, Bacon outlined his method for studying facts to interpret natural phenomena as an alternative to Aristotle's logic in the six books of the *Organon*, which subordinated natural philosophy to syllogistic logic. As outlined in the *New Organon*, Bacon's method consisted of four steps. First, one brackets all presuppositions and preconceived notions that could influence the objectivity of interpretation. Next, one describes the facts. Third, one uses the tables of discovery to categorize the facts according to the presence, absence, and degree of the characteristic under study. In this step, one makes a list of things or situations in which the phenomenon occurs and does not occur and the degree to which it occurs in each list. Once the facts are categorized, one eliminates all the characteristics that are associated with the phenomenon in order to isolate the cause of the phenomenon. From interpreting these lists, one can deduce the form, or underlying cause, of the phenomenon. This hypothesis becomes one of many such hypotheses that by

gradual degrees get closer to the true cause of a phenomenon.

Bacon's method and philosophy formed the intellectual foundations of modernity. His unflinching faith in the explanatory power of quantitative information remains ingrained in the masses, and his understanding of experience as the sole source of knowledge remains ingrained in the academy. Bacon's rejection of Aristotle's idea of formal cause, where change is caused by the form of the thing that changes, paved the way for modernity's repudiation of tradition, whereby the accumulation of facts through experience is what leads to human knowledge acquisition.

If Bacon is the father of modernity, then the guiding narrative of modernity is not the *polis*, as in classical antiquity, or the church, as in the Middle Ages, but faith in progress, efficiency, and individual autonomy. The Baconian method embodies the contradictions of the modern world; that is, that mastery over the natural world is a Faustian endeavor. Bacon transforms reason from a defining quality of the human condition in Aristotle, to a means to achieve the end of scientific progress in the form of quantitative information. Bacon sought to liberate humanity from the quicksand of tradition and the ancient and medieval "cult of books" to create the conditions for a modern world that revolves around objective experimentation. Bacon's emphasis on the utility of knowledge and power over nature led to a new quantitative economy that bridges the gap between an ancient and medieval economy that is naturalistic, organic, qualitative, and concrete to a modern economy that is materialistic, mechanistic, quantitative, and abstract.

René Descartes

Together with Bacon, René Descartes has influenced the intellectual trajectory of quantitative information. In his *Discourse on the Method* (1637), Descartes attempts to arrive at a fundamental set of principles that one can know as true without any doubt. Through systematic and methodological doubting laid out in the *Discourse*, one of the first philosophical texts written in the vernacular French and not in Latin, Descartes concludes in the *Meditations on First Philosophy* (1641) that if he doubted, then something or

someone must be doing the doubting, and therefore the very fact that he doubted proved his existence. Descartes argued he can be certain that he exists because he thinks: *cogito, ergo sum*. Descartes held that the mind alone was capable of grasping the truth with mathematical certainty, and morality was a science with its roots in metaphysics.

For Descartes, experiment, scientific inquiry, and action trump disputation, rhetoric, and speculation. These emphases became the backbone of 19th-century science and the impetus for modern society. Rhetoric itself could not produce truth with mathematical certainty and was relegated to communicating the principles that only science could discover. Rhetoric disturbs the clarity of rational thought and is nonphilosophical in its preoccupation with contingencies rather than eternal truths.

Upon the foundations of Euclidean geometry, Descartes synthesized algebra and geometry to develop analytic geometry. Using Descartes's analytic *geometry*, as articulated in *Geometry*, an essay accompanying the *Discourse*, one can formulate equivalent problems using algebraic equations and geometric shapes by manipulating their mathematical languages. Descartes's coordinate system allows one to map the locations of geometric forms such as points and lines using pairs of quantitative coordinates. The distances, areas, and volumes of geometry could be defined using numbers and expressed using equations.

Descartes aimed to re-legitimize philosophical discourse and scientific method in response to skeptics such as the Greek physician and philosopher Sextus Empiricus and, later, French essayist Michel de Montaigne, who argued in his *Essays* (1580) that the sources of human knowledge are unreliable. In the *Meditations*, Descartes reflects on all of the falsehoods he has believed in his life and all of the beliefs that could be proven false; he aims to start from scratch with what he can be absolutely certain of with no doubt. He argues that any belief that is uncertain or potentially proven wrong must be discarded. For instance, authorities and tradition cannot be trusted because authorities are frequently wrong. The senses cannot be trusted because sensible objects often appear skewed under water or from a distance. Immediate experience cannot be trusted because it may be a dream. Finally, mathematical truths such as $2 + 2 = 4$ cannot be trusted

because God may have created imperfect conceptions of mathematics. Even if there is no God, it is more likely that the senses would be imperfect if they were not created by a perfect Being.

Descartes concluded that the only thing he could be absolutely certain of with no doubt was the intuition that, even if he was being deceived, that someone or something was thinking. For Descartes, then, the *cogito* is the only self-evident truth. However, any other idea that proves the existence of something as clearly and distinctly as the *cogito* proves the existence of the self cannot be doubted. In his epistemological project in the second part of the *Discourse*, Descartes separates the immortal mind and the mortal body and argued that anyone can use reason to discover the truth. Knowledge is like a tree with its roots in metaphysics, trunk in physics, and the branches as the higher forms of scientific knowledge that house the fruit of knowledge. In the third part of the *Discourse*, Descartes offers a provisional—and later final—moral code that requires that one obey the laws and the customs of one's country and religion, be firm and resolute in holding true to the opinions one adopts, change oneself before attempting to change the world, and always chase the truth using the method of universal doubt.

Isaac Newton

Isaac Newton adhered to Descartes's code. As a cosmological framework, Newtonian mechanics undergirds the belief in scientific progress as the guiding narrative of modernity. Newtonian mechanics explains the motion of bodies according to the gravitational, electrical, and magnetic forces exerted on bodies when in motion and at rest. Just as the staying power of Euclidean geometry into the 19th century was due in part to its consistency with human experience, the success of Newtonian mechanics in accurately describing the motions of phenomena from celestial bodies to ordinary objects on earth and to atomic and subatomic matter is due in part to its compatibility with human intuition.

In his *Principia*, Newton proposed his laws of motion and equilibrium, which would become the laws of conservation of energy, momentum, and angular momentum central to modern physics.

Newton's first law is the principle of inertia proposed by Galileo and tweaked by Descartes. Newton's second law concerns force, mass, and acceleration and produced one of the most famous equations in history, F (Force) = m (mass) a (acceleration). Newton's third law states that for every action on a body at rest, in uniform motion or in accelerated motion, there is an equal and opposite reaction. Together, these laws set forth in the *Principia* form the basis of Newtonian mechanics, which, as a system, has provided the language and the intuition of scientists for three centuries.

Comte and Social Science

Guided by the spirit of the scientific revolution spearheaded by Galileo, Bacon, Descartes, and Newton, French philosopher Auguste Comte grounded not only the natural world but also the social world in quantitative information. Comte draws parallels between the intellectual maturations from infancy to adulthood of individuals and all of humankind as a model for the sciences.

For Comte, this maturation advances in theological/mythical, metaphysical/philosophical, and scientific/positive stages. In the theological/mythical stage, supernatural deities explain natural phenomena. In this stage, humans attribute the causes of unexplainable phenomena to anthropomorphic and divine beings in the image of themselves. The theological/mythical stages consist of three sub-stages: from fetishism, polytheism, and monotheism, representing the development of knowledge from worshipping inanimate objects to worshipping many gods of different natural phenomena to worshipping one omniscient God. In the metaphysical/philosophical stage, abstract and impersonal concepts define natural phenomena. For instance, Plato contrasts the imperfect world of appearances with the perfect realm of ideal Forms. The metaphysical/philosophical stage abstracts God from the world and replaces Him with an abstract God that directs the actions of the world.

In the scientific/positive stage, empirical observations, informed hypotheses, and replicable experiments explain natural and social phenomena. In this stage, humans induce laws from patterns and regularities in nature and

society and use the descriptive laws to make sense of particular cases. For Comte, humankind only reaches intellectual maturity in the third stage by discarding theological explanations for phenomena in the natural and social worlds and committing to the logic and rationality of the scientific method. Whereas Descartes viewed knowledge as a tree with metaphysical roots and a physical trunk supporting the branches of science, Comte arranged the sciences into a pyramid with mathematics at the base, followed by the physical, natural, and cerebral sciences, and culminating in social science. Comte saw himself as rescuing *sociology* from the uncertainties of philosophy and linking it to the certainties of science.

INSTRUMENTALISM

According to instrumentalism, the value of any particular theory does not rest in its ability to capture truth but in its usefulness for understanding and predicting phenomena. On this view, the real worth of a theory is not in its truth or approximation of reality but in its value as a useful instrument in solving practical problems. The natural and social sciences are widely appreciated because of their capacity to provide solutions to many of the problems humans face. Even for those issues humans are not sure science has been able to explain, there is the belief that science will one day achieve breakthroughs and those problems will be solved. This entry traces the origins of instrumentalism and its engagement with pragmatism and scientific realism and concludes with a brief account of the emergence of a related development in scientific theory, namely, constructive empiricism.

Origin and Significance

Instrumentalism and the related tradition of pragmatism are associated with the American philosophers William James (1842–1910) and John Dewey (1859–1952), whose works greatly influenced philosophy, psychology, education, and civil society. Pragmatism understands that knowing the world is inseparable from agency within it, that philosophical concepts should be tested by scientific experimentation, and that a claim is true only if it is useful. According to Dewey, instrumentalism is the position that all the acceptance of a given theory amounts to is a judgment about the theory's usefulness in predicting phenomena. Relatedly, scientific realism holds that the world as described by science is the actual real world, regardless and independent of what humans imagine and think it is.

Although instrumentalism is in constant engagement with both pragmatism and scientific realism, it is different from them as it considers, largely, that ideas are appreciated by their transformative capabilities as instruments of change with positive consequences. Instrumentalism is methodological and outcomes focused. It is about doing and action rather than abstract thoughts. According to instrumentalism, theories are not actually truth-evaluable, and they do not always correctly depict reality. The truth of an idea is thus determined by its success in actively providing solutions to problems, while its real value is determined by the roles of ideas in enhancing human experiences.

Scientific Realism and Instrumentalism

A closer consideration of scientific realism may be helpful for understanding instrumentalism. *Realism* holds that there are mind-independent objects. *Scientific realism* is the idea that scientific theories say definite things about genuinely existing entities and that scientific theories get successively better and better at giving a true account of the world. Hence, its reliance on abductive reasoning, or “inference to the best explanation,” has led to the success of science in providing true, or approximately true, descriptions of the world. In contrast, instrumentalism maintains that even a successful scientific theory discloses nothing that is either true or false about unobservable processes or objects; rather, a theory is only a tool for predicting observations, which lead in turn to the formulation of “laws” that these phenomena supposedly obey. For instrumentalists, there is a world of difference between observable and unobservable entities even though they concur with the realists' explanation of observable entities. The major difference lies in the unobservable entities, because instrumentalism considers unobservable entities as merely posited entities based on theoretical considerations. For scientific realists, it is impossible to draw a distinction between the two, for they lie on a continuum and are mutually reinforcing in any effort to make sense of the world. Furthermore, for scientific realists, even when entities and ideas do not serve an immediate practical purpose, this does not diminish their philosophical relevance. Indeed, to reduce the ideas and entities to the level of *tools* diminishes the philosophical

relevance of ideas and negates the role of the philosopher in making sense of the world.

Among the better-known scientific realists is the physicist Wolfgang Pauli (1900–1958), famous for his *exclusion principle*. In essence, according to this principle, no two fermions (elementary particles with “half-integer spin”) in an atom can have the same four quantum numbers; in other words, only one fermion can occupy a particular quantum state at a given time. After decades of systematic observations, many scientists have come to accept that the Pauli exclusion principle is true, although other scientists have not.

Within the philosophy of science, instrumentalism has benefited from the thinking of late 19th- and early 20th-century thinkers such as the physicists Ernst Mach (1838–1916), who believed that physics should be based entirely on directly observable phenomena, and Pierre Duhem (1861–1916). Duhem, in his book *The Aim and Structure of Physical Theory* (1906), held that the physical sciences should be practiced independently of deep metaphysical assumptions. That is, the aim of physical theory is to propose mathematical laws that predict experimental outcomes as precisely and simply as possible. It’s not necessary to believe that the fundamental physical laws are true but rather that they are merely useful fictions that help scientists predict phenomena.

Later Developments

Instrumentalism is dynamic and has continued to develop over time. Even in the face of philosophical antagonisms, what has persisted is the central thesis of instrumentalism that sees theories as tools for pursuing practically useful purposes rather than as correct and true descriptions of the world and nature. On those grounds, instrumentalism is an extreme view of how to think about the nature of scientific theories, as evaluable only in terms of their use as tools of inference. More generally, anti-realism doesn’t commit itself to the existence or reality of the things mentioned in theoretical descriptions but values the theories for other reasons having to do with empirical adequacy, utility, and any number of other theoretical virtues not involving a belief in the entities of the theory.

Constructive empiricism is a prominent version of this class of interpretation of theories. Developed and discussed by the philosopher of science Bas van Fraassen, it became widely known after the publication of his book *The Scientific Image* in 1980. The main contribution of van Fraassen through constructive empiricism is that of actually finding a balance between scientific realism and instrumentalism. In his position on theories as tools, he insisted that just as scientific realism is right in its metaphysical view of scientific theories, so instrumentalism is also correct and equally reasonable epistemically.

According to van Fraassen, the goal and aim of science is to provide theories that are empirically adequate. For a theory to be empirically adequate, it must be right about the observable phenomena. Indeed, many of the theories that are adopted by scientists are only adopted for their empirical adequacy in serving as explanatory frameworks and not necessarily because one believes in them entirely as true. Furthermore, constructive empiricism holds that scientific theories are semantically literal (i.e., its propositions are either true or false) and are adequate only if everything they say about observable entities is true.

Perhaps the chief difference between early and contemporary instrumentalism is a matter of emphasis. For instance, while Duhem’s strand of instrumentalism insisted that the objective and purpose of physical theories ought to be instrumental, van Fraassen holds that the aim and objective of physical theory could actually be instrumental. van Fraassen’s contemporary instrumentalism has thus only balanced the philosophical axis and continuum of both scientific realism and instrumentalism, particularly through the position that it is also about the rationality of the philosophers in question and their capacities for philosophical accommodation. Thus, van Fraassen preserved the original view of instrumentalism, maintaining the view that instrumentalism remains largely the best approach to making sense and understanding science philosophically.

INTERPRETATION

The *interpretation* of a theory assigns meaning to some or all components of the theory by connecting them to independently interpreted statements or theories, or directly to the world. As this entry explains, the precise kind of connection depends on whether the theory is mathematical or empirical, on whether it is expressed informally or formally, and on the kind of formalism. The interpretation of a mathematical theory connects it to another theory, typically with the goal of showing how specific formal properties from one of the theories transfer to the other. Such an interpretation is well defined and uncontroversial. The interpretation of an empirical theory, on the other hand, is an empirical phenomenon that relates not only to semantic aspects like the content of the theory and its conditions for confirmation but also to pragmatic aspects

like the behavior of the scientists and the teaching and learning of the theory. Accordingly, an account of the interpretation of empirical theories needs to relate to these semantic and pragmatic aspects, and there is significant debate about every extant account of the interpretation of empirical theories.

The Interpretation of Mathematical Theories

A mathematical theory is typically interpreted by relating its expressions to other mathematical expressions. Such an interpretation may proceed by formal semantics or by the interpretation of one theory in another. Therefore, this kind of interpretation stays within the purely formal realm. *Interpretation* sometimes also refers to the connection of a mathematical theory to genuine mathematical objects, which are not purely formal but also not part of the physical world.

Formal Semantics

If a theory is formally axiomatized in predicate logic, it can be easily interpreted by interpreting its constant, predicate, and function symbols—in other words, its *vocabulary*—in the formal semantics developed by Alfred Tarski. A very simple theory in predicate logic may contain only the single sentence $Pa \wedge \exists x Qxa$ (“ a is P and there is an x such that x has the relation Q to a ”), where a is a constant symbol, P is a one-place predicate symbol, Q is a two-place predicate symbol, and x is an existentially quantified variable. Thus, the theory's vocabulary consists of a , P , and Q . A structure for the theory in formal semantics then consists of a domain and an interpretation. The domain is a set of objects like $\{\alpha, \beta, \gamma\}$. The interpretation assigns to each constant symbol an element of the domain; a could, for instance, be assigned α . To each one-place predicate symbol, the interpretation assigns a subset of the domain; P could, for instance, be assigned $\{\alpha, \beta\}$. To each two-place predicate symbol, the interpretation assigns a set of pairs from the domain; Q could, for instance, be assigned $\{\langle \alpha, \beta \rangle, \langle \beta, \beta \rangle, \langle \gamma, \alpha \rangle\}$. The structure then determines whether the theory is true or false, which is the theory's *truth value*.

The theory is true if and only if all its sentences (in this case just the one sentence) are true. The truth value of each sentence is determined by the truth values of its subsentences, in this case Pa and $\exists x Qxa$, and the logical connectives connecting them, in this case “ $\wedge$.” Pa is true if and only if the object assigned to a is an element of the set assigned to P , which it is, since $\alpha \in \{\alpha, \beta\}$. $\exists x Qxa$ is true if and only if there is an object in the domain such that the pair consisting of that object and the object assigned to a is an element of the set assigned to Q , which it is, since $\langle \gamma, \alpha \rangle \in \{\langle \alpha, \beta \rangle, \langle \beta, \beta \rangle, \langle \gamma, \alpha \rangle\}$. The whole sentence $Pa \wedge \exists x Qxa$ is a conjunction, and a conjunction is true if and only if both its conjuncts are true, which in this case they are. Thus, the sentence is true in the structure, and the theory consisting of only this sentence is also true in this structure, which is therefore called a model of the theory. (For this reason, formal semantics is also called model theory.) More complicated theories can also involve function symbols and higher order predicate symbols, that is, predicate symbols that apply to constant, predicate, and function symbols rather than only to constant symbols. The basic idea of formal semantics stays the same for such more complicated theories.

If a mathematical theory is well established, like the theory of the natural numbers, for instance, then it is often taken to have a standard model. In the case of the natural numbers, the domain of this standard model is just the set N of natural numbers, the constant symbol “42” is interpreted by the number 42, the two-place predicate “ $>$ ” is interpreted by the set of pairs in which the first is greater than the second, the function symbol “ $+$ ” is interpreted by the function that maps each pair of natural numbers to the sum of its components, and so on. The domain and the entities that interpret the vocabulary of such a standard model are then sometimes taken to exist as genuine mathematical objects, independently of any formalization. They may be taken to exist, for instance, as platonic objects or as objectively real and abstract products of the human mind, as was suggested by Karl Popper. A theory of, say, geometry may thus be interpreted by points and lines in a platonic space or Popper’s world of objective ideas. If the points and lines were part of the physical world, however, the theory would be empirical.

The Interpretation of Theories in Other Theories

A mathematical theory can also be interpreted more generally by mapping its expressions to the expressions of another mathematical theory and by mapping its structures to the structures of the other mathematical theory. Such an interpretation is often used to infer that one of the theories has a specific feature, such as consistency, if the other one does. A theory of geometry, for instance, can be interpreted by vectors of real numbers. Another standard example is the interpretation of the complex numbers as pairs of real numbers. Here, pairs of real numbers are mapped to complex numbers, and every expression referring to a complex number is mapped to an expression referring to a pair of real numbers. The expression about the complex numbers is then true if and only if the expression for the real numbers is true. Since two real numbers make up one complex number in this interpretation, the interpretation is called *two-dimensional*.

More generally, n -tuples (ordered sets with n elements) of one Class A of structures can be used to interpret the elements of the domains of another Class B of structures. This interpretation then leads to an n -dimensional interpretation of the theory of Class B in the theory of Class A .

The Interpretation of Empirical Theories

An interpretation of an empirical theory consists of a connection between the theory and the empirical world; specifically, an interpretation describes what the world would be like if the theory were true. The interpretation of a theory expressed informally in natural language is typically simply taken over from the interpretation of the natural language, but the theory may also be interpreted in analogy to the interpretation of a formally expressed theory. The interpretation of a formally expressed theory can conversely consist of the translation into a natural language, whose interpretation thereby also applies to the theory. (This is an informal analogue to the interpretation of one mathematical theory in another; instead of mapping the expressions of a formal theory to expressions of another formal theory, the expressions of a formal theory are mapped to expressions of natural language.) But a formally expressed theory can also be

interpreted formally, in which case the kind of interpretation depends on the formalism used.

Syntactic Theories

A theory syntactically described in predicate logic can be formally interpreted in model theory. But since an empirical theory has to be connected to the world in some way, the structures interpreting the theory either have to be in turn connected to the world through some interpretation, or the structures themselves must be what may be called *worldly*. For a *worldly structure*, at least some elements in its domain must be objects of the world or some of its sets of objects or sets of tuples of objects must correspond to properties or relations that can be found in the world. In the simplest case, the domain contains only objects of the world, each predicate symbol is interpreted by a property of or relation between the objects in the world, and each function symbol is interpreted by a function that holds between objects of the world. The theory is then true if and only if these objects, properties, relations, and functions make up a worldly structure in which the theory is true.

Already this simplest case gives rise to a central problem for the interpretation of theories, the impossibility of a theory fixing its own *intended interpretation*. The reason for this impossibility is known as Putnam's *model-theoretic argument*, which relies on the isomorphism theorem. Roughly, two structures are *isomorphic* when one can be obtained from the other simply by uniquely exchanging the objects in their domain and in the set-theoretic entities the interpretation assigns to the vocabulary. Thus, the structure mentioned earlier with domain $\{\alpha, \beta, \gamma\}$, which interprets a by α , P by $\{\alpha, \beta\}$, and Q by $\{\langle \alpha, \beta \rangle, \langle \beta, \beta \rangle, \langle \gamma, \alpha \rangle\}$, is isomorphic to the structure with domain $\{\beta, 2, k\}$ that interprets a by β , P by $\{\beta, 2\}$, and Q by $\{\langle \beta, 2 \rangle, \langle 2, 2 \rangle, \langle k, \beta \rangle\}$. This is because the second structure can be obtained from the first by replacing α by β , β by 2 , and γ by k . This mapping between the two sets $\{\alpha, \beta, \gamma\}$ and $\{\beta, 2, k\}$ is a bijection (also called a *one-to-one and onto mapping*). Whenever two sets have the same number of elements and that number is greater than 1, there are multiple bijections between these sets. In particular, any element of the one set can be mapped to any element of the other set in some bijection.

And as the earlier example indicates, for every bijection between the domain of a Structure A and some Set S , there is another structure that has the domain of S and is isomorphic to A . For instance, a might not only be interpreted by β but also by 2 or by k , depending on the bijection between the two domains. The isomorphism theorem now states that if a theory is true in some Structure A (has the Model A), then it is true in every structure that is isomorphic to A . And this entails that every true theory has infinitely many models, and in particular every constant, predicate, and function symbol could be interpreted by something completely different: Even if a is intended to be interpreted by α , there is another model in which it is interpreted by β , another in which it is interpreted by 2 , another in which it is interpreted by k , and yet another in which it is interpreted by Liechtenstein.

Because of the model-theoretic argument, the intended interpretation of a theory needs to be fixed at least to some extent without recourse to sentences of predicate logic, for instance, by simply pointing to the objects by which a symbol is to be interpreted. This is known as an *ostensive interpretation* (or sometimes, confusingly, an *ostensive definition*). Ostensive interpretations are obviously only feasible for symbols that are intended to be interpreted by objects that can be pointed at. For predicates which apply to sets that are so large that it is not feasible to point at all their elements (say, infinite sets), ostensive interpretations have to be complemented. This complementation often takes the form of psychological similarities between those who teach, say, a predicate and those who learn it so that the grouping of objects the teacher intends to convey is picked up by the student. However, such complementations typically lead to areas of vagueness so that for some objects it is not clear whether they do or do not fall under the predicate. Fortunately, the formalism of standard model theory can be generalized to allow for vague interpretations. In a standard interpretation, a one-place predicate symbol is assigned a single set of objects, all of which have the property corresponding to the predicate symbol; a many-place predicate symbol is assigned a set of tuples of objects, all of which stand in the relation corresponding to the predicate symbol. In a vague interpretation, each predicate symbol is assigned two

disjoint sets: One containing (tuples of) objects that clearly have the corresponding property (stand in the corresponding relation), and one containing (tuples of) objects that clearly do not have the property (do not stand in the corresponding relation). For (tuples of) objects in neither of these two sets, it is vague whether they have the property (stand in the relation). Similar generalizations exist for function and constant symbols.

In the *received view of theories*, which assumes that the theories are syntactically expressed, the interpretation of a theory is itself described to a large extent syntactically: The logical relations of the theory's vocabulary to another independently interpreted vocabulary is described in predicate logic. The predicate-logical sentences describing these relations are often called *correspondence rules*, but are also known as *coordinating definitions* (although they are typically not definitions). The interpretation of the theory's vocabulary (the *theoretical vocabulary*) is then determined indirectly by the interpretation of the independently interpreted vocabulary and the correspondence rules. If the correspondence rules provide explicit definitions for every predicate, function, and constant symbol of the theory in terms of the independently interpreted vocabulary, then every model-theoretic structure for the independently interpreted vocabulary determines a unique structure for the theory. Typically, however, correspondence rules do not provide explicit definitions for the vocabulary of a theory, in which case the independently interpreted vocabulary only determines a class of structures for the theory. In this case, the theory is called *partially interpreted*.

If the received view of theories is combined with *semantic empiricism*, the independently interpreted vocabulary is assumed to be observational and thus can be interpreted by ostension and some complementation for large sets. Accordingly, the independently interpreted vocabulary may be vague, leading to a vague interpretation of the theory even when every symbol in the theory's vocabulary can be explicitly defined in the independently interpreted vocabulary. If the independently interpreted vocabulary is only informally interpreted, the theory itself is informally interpreted by applying the informal rules of interpretation to the correspondence rules.

Semantic Theories

A theory can also be described semantically with model-theoretic structures (or, essentially equivalently, set-theoretic structures), which are then called the *models of the theory*. For semantically described theories, one typically speaks of *representations* rather than *interpretations*. There is an extensive literature on how to define representation—that is, how to distinguish relations that are representations from relations that are not. The following paragraph focuses on how to describe representations and thus assumes that a representation is already identified as such.

The representation relation between the models of the theory and the world may be an informal one, for instance, a similarity relation. More often the interpretation relation is assumed to be formal, a mapping from the models of the theory to other model-theoretic structures. As for syntactic theories, these other model-theoretic structures either in turn have to be connected to the world through some interpretation or have to be worldly structures. In the simplest case, the domain contains only objects of the world, each set corresponds to a property of or relation between objects in the world, and each function holds between objects of the world. The representation relation can be simply one of isomorphism: For each (or some) model of the theory, there is a bijection (a one-to-one and onto mapping) from its domain to the objects in the world so that each element of each set of the model of the theory is mapped to a unique element in a corresponding set of the structure of the world. Weaker mappings are possible, for instance, mappings that are not one-to-one or not on to.

Like syntactic theories, semantic theories cannot fix their own intended representations. The reason is analogous to the model-theoretic argument and can be illustrated particularly simply under the assumption that the representation relation is an isomorphism. Then a theory correctly represents the relevant aspect of the world if and only if the model of the theory is isomorphic to the structure W of the relevant aspects of the world. But again, for any set S with the same number of elements as the domain of W , there is a bijection from the domain of W to S , and a corresponding structure V with S as its domain that

is isomorphic to W . Then the model of the theory is also isomorphic to V . As for syntactic theories, then, every element of the semantic theory can represent any object whatsoever. For this reason, the intended representation of a theory needs to be fixed at least to some extent without recourse to model theory, for instance, by simply pointing to the objects that a set in the structure of the theory is intended to represent.

Informal Theories

If a theory is not completely formalized, be it in predicate logic or model theory, it can be first formalized in one of these ways and then formally interpreted as discussed earlier in this entry. But the interpretation of an informal theory can also proceed directly via the interpretation of the natural language in which it is formulated and therefore fall into the purview of linguistics and philosophy of language. There, the question of the definition of interpretation is also extensively discussed. One central assumption of this discussion is that interpretation is an intentional concept, and specifically dependent on the intentions of the person using the interpretation to, for instance, communicate the content of a theory to someone else. This assumption of intentionality occurs analogously in the debate on the definition of representation.

Restricting Interpretations

Interpretations of empirical theories can go beyond the theory proper in restricting the way the world could be so that one theory can have different interpretations. In this case, if the theory were true, according to one interpretation the world would be different from the way the world would be according to another interpretation. Such competing interpretations exist, for instance, for quantum mechanics.

INTUITION

Intuiting can be conceptualized as a way of direct knowing, that is, knowing “without any use of conscious reasoning” (Sinclair & Ashkanasy, 2005, p. 357), through a process that seems to bypass sequential (i.e., step-by-step) reasoning. Although the terms *intuiting* and *intuition* are often used interchangeably, it is important to differentiate between them. Whereas intuiting is the process of *direct knowing*, intuition is the outcome of this process. Top professionals in any area of expertise, including scientists, engineers, business managers, musicians, chefs, athletes, and designers, are esteemed precisely for their *sense of the game* in their domains, even when formally they are recognized for performance. Yet, until recently, it was mainly philosophers who advocated for intuition, while the scientific community was wary of it.

What Is Intuition?

Nowadays, numerous scientists admit to relying on intuition as a part of scientific inquiry. In fact, based on interviews with 20 top scientists, including 17 Nobel laureates, Viktor Dörfler and Colin Eden (2019: 538) assert that “no significant research result seems to have been achieved without intuition playing a major role in the process.” The interviewed Nobel laureates offered examples of using intuition in some form in their work, such as their ability to see simple patterns in complex situations. These examples, while not necessarily labeled as intuition, fit the description of direct knowing without sequential reasoning or understanding how the knowledge was obtained.

Scholars generally agree about recognizing patterns with which an intuitor had previous experience; this is often referred to as *expert intuition*. Some scholars, however, argue that experts may also identify previously unseen patterns and, further, can create new patterns that did not exist before, which is the basis of creative intuition.

Contemporary scholars agree that people tend to go back and forth between intuitive and nonintuitive modes of working through things, a thesis that was proposed decades ago by both Michael Polanyi and Henri Bergson, two

scientists-turned-philosophers who advocated for intuition. Intuition frequently endures unfounded criticism of being recklessly impulsive and ignoring facts. Contrary to this misrepresentation of intuition, research shows that scientists, much like investors, typically diligently analyze available data, as well as use intuition to sense the validity of their assessments. Intuiting is far from acting on a whim; it is an elaborate, highly complex process that incorporates facts and processes them in a holistic way. Perhaps the very reason for the non-conscious nature of intuiting is that the conscious mind is not always capable of the level of complexity often required for situations at hand. Even in highly quantitative domains, such as experimental science, software engineering, and finance, intuitive decision makers frequently use stories rather than computations to frame their decisions. Gary Klein describes intuitive decisions taken by firefighters: They take calculated risks rooted in elaborate perceptions. Laura Huang and Jone L. Pearce, based on their study of angel investors, suggest that decision makers who use intuition in their practice, are less likely to miss seemingly trivial details that are in conflict with analytical presumptions about a situation; these details often provide essential clues about investment outcomes. A number of prominent intuition researchers approached intuition by exploring some of its components that can allegedly be measured, while others moved on to exploring the sensory, experiential aspects of intuition. Intuition is less of a construct to be measured and quantified, and more of a phenomenon to be observed, sensed, and synced with in order to understand its nature.

What Intuition Is Not

When dealing with something new, one way to explain it is through what it is not, demonstrating how this new entity is not like the known entities; initially, there is a lack of vocabulary to explain the new entity. In line with this logic, it is important to point out that intuition is *not random guessing*. In guessing, none of the solutions is recognizable, but during intuiting, some solutions may produce psychophysiological coherence or an adverse response. If the response is accurately interpreted, it can be useful in selecting a preferred option. Importantly, intuition is correct far more

often than the probability of random guessing. Intuition is not instinct; unlike *instinct*, which is hardwired and is always unconscious, the quality of intuition can improve as one's experience increases. Intuition is also not *heuristics*. In contrast to heuristics, which means applying a pre-defined rule to a specific situation, intuition is adaptive and may involve recognition of patterns not seen before. Related to this, intuition is also unlike *biases*, which are tacitly held preferences that manifest in specific decision situations. This does not mean that intuition is never biased, since complex pattern recognition may involve biases, as shown by Amos Tversky and Daniel Kahneman (1974), but sequential reasoning can be equally subject to biases. Intuition is more than just a *gut feel*, although it is often described as something felt at the pit of one's stomach; intuiting can involve one's whole body. Jennifer Frank Tania proposes that intuition is not simply a gut feel, but rather, a whole-body experience, extending into space around the subject's body as well as into the imaginary realm.

Further, intuition is not a *sixth sense*, as it is often described. Intuition seems to make use of all of our senses and capacities. Intuiting is not *super-natural*; what is understood about intuition can be explained in terms of people's natural abilities to perceive themselves and their environments. Neither is intuition *extrasensory*, as it relies on the body's psychophysiological system, including senses of vision, hearing, taste, smell, and touch, in addition to other senses, to receive information or make sense of something without resorting to sequential analysis. Some discomfort with the subject of intuition may be due to its association with underresearched and underexplained phenomena like remote viewing, telepathy (e.g., mind-to-mind communication), and precognition (sensing future events). Although studies related to these topics still remain marginalized, broader intuition studies and projects are gaining acceptance, ranging from getting published in top journals like *Human Relations* to being explored by the U.S. military.

Intuition is often contrasted with analysis, which is incorrect. The opposite of analysis, which dissects something to examine its parts, is *synthesis*, which fuses separate parts into a larger phenomenon to understand a bigger picture. Although intuition can involve synthesis, the two are not the same.

Intuitive Judgment and Intuitive Insight

In the management literature on intuition, there appears to be an underlying assumption that all intuitions are judgments. This neglects a possibility of intuitive insight, the "*aha* moment" resulting from intuiting rather than from deliberate sequential reasoning. Dörfler and Fran Ackermann put forth a notion of *intuitive insight*, suggesting that insights can be both intuitive and nonintuitive, much like judgments that can be intuitive and nonintuitive. Often both intuitive insight and intuitive judgment appear in addressing a problem. For example, a decision maker can create new solutions through intuitive insights and then judge alternative solutions intuitively or otherwise. In another example, expert chefs rely on both intuitive judgment and intuitive insight to consistently produce creative, original, interesting food experiences; chefs may use intuitive insight to envision new dishes, and intuitive judgment to decide whether these dishes may work out in the context of their restaurants.

Features of Intuiting and Intuition

Currently, it seems that intuition research is being informed by practice more than the other way around; the most useful and relevant data on intuition are gathered through interviewing, observing, and surveying expert practitioners. For instance, it was primarily through interviewing decision makers and creative problem solvers that intuition researchers reached a consensus (for the time being) on six necessary features of the process of intuiting and its outcome, intuition:

- Intuiting is *rapid*, meaning that it occurs almost instantaneously, and in this respect, it is similar to guessing. However, it is guessing which is *frequently correct* (in line with Simon, 1983, p. 25).
- Intuiting is *logical*, meaning that it operates independently of the general principles of reasoning that we call logic; therefore it is neither *logical* nor *illogical*, as it neither follows nor contradicts the rules of logic. In deliberate sequential reasoning, we work our way through the logical connections from a particular

problem to the idea that addresses it, while intuiting leaps to the solution.

- Intuiting is *tacit* in the sense that intuitors can describe the outcome but not the way they arrived at it. Although intuitors are often good at defending their intuitive judgments or insights, there is no evidence that the justification has anything to do with the way the intuiting was used. The tacit quality of intuiting suggests that the process of intuiting takes places outside the scope of the conscious mind, which is why it is also referred to as *nonconscious*.
- Intuition is *holistic* or *gestalt*, as it is about the *big picture*, including broad context, and far-reaching implications. It even takes into account items inaccessible to deliberate sequential reasoning, sometimes referred to as the *unknown unknowns*. Furthermore, intuiting also involves the totality of the intuitor's experiences.
- Intuition, as the outcome of intuiting, has an *intrinsic certainty*: Intuitors are confident they have the right answer (or one right answer). Even though intuition often brings with it a *feeling of knowing*, this does not make intuiting infallible, and intuitors do not usually claim infallibility. Robert A. Burton (2009, p. 101) points out that the *feeling of knowing* can occur with both proven and unproven insights and is not a reliable indicator of accuracy.
- Finally, intuition, as the outcome of intuiting, is considered to be *spontaneous*. This means that intuiting does not require conscious effort at the moment when it happens. This is the one feature on which intuition scholars (academics who study intuition empirically) and intuition practitioners (those who tap into their intuition in their practice) disagree. The spontaneous nature of intuiting has recently been brought into question, as intuition practitioners have been reporting intentional summoning and use of intuition. The two contradictory views may be reconciled by allowing for the *spontaneous nature* of intuition, that is, useful and relevant information emerging into consciousness without deliberate effort, and the *intentional use of intuiting*, in other words a process of deliberately conjuring the process of intuiting on cue.

Besides these six features of intuiting, it is also often mentioned that intuiting is frequently

accompanied by somatic (visceral) effects and affective charges. Whereas the role of affect in intuiting and intuition has been addressed, the somatic aspects are much less understood. It seems inevitable that some aspect of somatic experience will soon be added to the list of the aforementioned six characteristics.

Facets of Intuitive Awareness

The phrase *facets of intuiting* refers to the various pathways through which intuitive messages arrive or become known to an individual. For the physical facet of intuiting, Frances Vaughan suggests that one may notice muscle tension, stomachache, or back pain seemingly not in response to anything in the environment of which the person is aware (1989, p. 47). This lack of congruence between somatic experience and either the environment or one's mental state may prompt one to examine more closely what is going on beyond the obvious.

Vaughan clusters together both emotions and feelings in the emotional facet of intuiting. For instance, one may feel safe in some place or in presence of a particular person, or to the contrary, one may experience a sudden emergence of anger with a person, seemingly without reason. Vaughan suggests learning to recognize our emotional states, and notice how one feels, as these feelings may affect perceptions, memories, and interpretations. There is some disagreement among scholars regarding the role of affect in intuiting: whether it always accompanies intuition and whether its presence is prognostic or reactive. Marta Sinclair noticed that fluctuation of emotions can serve as a channel for intuiting rather than being an add-on to intuition. Huang and Pearce suggest that affect is a reaction to the level of decision maker's confidence in the decision.

The mental facet of intuiting is related to thinking: It could be an intuitive insight for a challenge that one is dealing with, or an unexpected thought, seemingly without a prompt from the environment, and not resulting from sequential thinking through ideas. This facet of intuiting is the most studied and the best understood, as it is the mental facet that provides account of both intuitive judgments and insights.

The spiritual facet of intuiting, according to Vaughan, is a transcendent, holistic form of

intuition. While there is no clear description of spiritual intuition, it probably closest to the notion of indwelling, that is, attending to the object of one's interest, much like being fully engaged in listening to a musical composition or exploring a work of art.

Interplay Between Intuition and Sequential Reasoning

Considerable gaps remain in our understanding of the dynamic between deliberate sequential reasoning and intuition. One concern that academics, practitioners, and corporate leaders have about employing intuition is that if intuiting becomes widely accepted as a valid way of knowing, students and employees may be tempted to use it as a substitute for rigorous analysis, logical argument, or deep thinking. While intuiting cannot replace all aspects of deliberate sequential reasoning, thinking and data crunching cannot replace intuition for types of problems that require a sensory or experiential component, like creating psychological safety in a team.

Until fairly recently, it was unclear whether intuition and deliberate sequential reasoning are two aspects of one continuum, or whether these are two separate dimensions, as the dual-process theories suggest. Early ideas of the interplay between intuition and analysis suggested a continuum, on which one would be either more or less intuitive. As more recent research indicates, intuition and deliberate sequential reasoning are likely *two separate dimensions*. One can be good or bad at both, or better at one than the other, relying on each dimension more or less, depending on one's level of expertise, the type of problem at hand, and the environment. Expert decision makers, scientists, design engineers, and other practitioners reconcile their intuition and formal reasoning by creating a cohesive narrative.

Factors Affecting Intuition

The quality of intuition is related to three factors: characteristics of the intuitor, the problem at hand, and the environment. Level of expertise is one of the most frequently discussed characteristics of an intuitor. "Intuiting becomes the dominant mode of knowing at the highest level of expertise" (Dörfler & Stierand, 2017, p. 4). A closer look at studies claiming to have provided

experimental evidence on the failure of intuition reveals that these experiments targeted intuition of novices. In contrast, studies that have found empirical evidence of intuition working well, typically focused on intuition of people at a high level of expertise (predominantly using nonexperimental methods, such as interviews and observations in natural context). Some researchers point out that a high level of expertise is necessary for good intuitions. Therefore, it seems that expertise fuels intuiting, enabling intuiting to become the dominant form of knowing.

In addition to expertise, other factors that influence intuiting on an individual level are attitude toward intuition (dismissive vs. accepting); physical, emotional, and intellectual self-awareness; and preference for intuitive versus sequential processing style.

Characteristics of problems and circumstances under which intuiting is the dominant mode of reasoning are typically those that do not allow the use of deliberate sequential reasoning, including uncertainty, limited data, no precedent, time pressure, volatility of the situation, high complexity, and ambiguity—in other words, the usual environment of today's organizations.

An organization's openness to intuiting and a cultural fit for use of intuition contribute to employees' willingness to employ (and disclose the use of) intuiting. Accountability to others seems to reduce the inclination of knowledge workers to rely on intuition. Organizational culture against intuiting as a way of knowing may lead to suppressing intuitions in an effort to conform or to get approval for the way the answers have been arrived at. However, the danger of downplaying or hiding the use of intuiting is in reducing transparency around the problem-solving process.

Intuition as Sensing Plus Sensemaking

Practice-based explanation of intuiting is founded on accounts of *intuition practitioners*—practitioners who have expertise in the use of intuiting and who consistently use intuiting in their practice, intentionally and on cue. Intuition practitioners see intuiting as a sensory-based *direct way of obtaining awareness* of phenomena. *Affect and visceral sensations* are essential to intuition practitioners: affective and visceral cues typically

serve as starting points that make intuition practitioners pay attention to intuiting. Intuition practitioners employ a sensory-based way of obtaining awareness of phenomena, achieving firsthand experience. For the purpose of this entry, we use the term *sensory* to mean “composed of the five primary senses, as well as visceral (e.g., hunger), affective (e.g., love), and mental sensations (e.g., pride).”

Although intuition practitioners may or may not describe intuiting as rapid, tacit, holistic, alogical, and having intrinsic certainty, as scholars do, they often talk about intuition as *both spontaneous and intentional*. For example, intuiting could be engaged by asking oneself a question about a situation, or defining a desired outcome, and staying attuned with soft focus to sensory and environmental cues emerging in response to the initial inquiry. After posing a question, practitioners may attend to shifts in their mental, physical, and affective states. These shifts seem to occur without apparent causes either from the external environment or from internal processes and hence are labeled as intuitive.

Someone not experienced with paying attention to sensing may wonder how it is possible to get intuitive information seemingly out of nowhere unless there is a way to justify it as expertise. Intuition practitioners suggest that, over time, a student of intuiting could learn to understand various sensations underpinning their intuiting. Consciously making sense of these sensations can create a useful, actionable narrative. As an analogy, to a musically challenged person, observing someone differentiate between F# and G in the third octave just by hearing the sounds may seem like a lucky guess or a sort of a magic trick. Similarly, when it comes to intuiting, it may seem just as mysterious to observe someone differentiate among the meanings of their sensory signals. To highly trained musicians, even the notion of confusing F# and G may seem strange because they perceive the two notes as two distinct sounds. Similarly, someone who is practiced in intuition is able to distinguish between an intuition about a positive resolution versus unfounded hope.

The academic literature on intuition treats intuition as a unitary construct. A more nuanced way to look at intuiting is in terms of a process composed of two phases: *sensing* and *sensemaking*,

resulting in intuitive judgment or intuitive insight. Expert practitioners of intuition who admit to using intuition in their work actively engage with both sensing and sensemaking.

The sensing phase of intuiting delivers signals which an attentive person can perceive as visual images, auditory sensations, phrases, and changes in physical and emotional state. Intuition arrives to each person in a language or form that is unique to that person, therefore it cannot be standardized. For example, the same visual image of a dog can represent protection to one person and fear to another, or it can mean different things to the same person in different contexts. Hence, if sensing is not followed by sensemaking, the product of sensing cannot be utilized for intuiting on cue. Sensemaking is concerned with revealing the meaning of sensed signals. The sense making phase appears to be tied to one's domain of expertise relevant to the particular situation (i.e., expert intuition). The pitfall of expert intuition is that experts may not be aware of the sensing part of intuiting, as they only perceive the signals of which they have already made sense. Thus, they do not distinguish between the *outcome of intuiting* and the *outcome of sensemaking*, being oblivious to the notion that intuiting as a whole includes not only sensemaking but also sensing. This may lead to a missed opportunity to improve intuiting by developing one's sensory awareness.

Conclusion

Knowledge workers in today's organizational environment must be prepared to operate in volatile, uncertain, complex, and ambiguous conditions. Under these conditions, best or satisfactory solutions for complex problems arise through cognitively flexible response rather than additional analysis; scientists, managers, and design engineers, for example, may need to use their intuition (knowing without knowing how) as they move through uncertainty. How can analytically minded practitioners become better at intuiting? They need to develop attention to *sensing* through enhanced awareness of their physical, emotional, and mental states, and they should advance their subject area expertise to improve *sensemaking*. At the highest level of expertise, it seems that

intuiting, supported by deliberation, is the predominant way of working through a problem. Yet, while Western education places great emphasis on teaching sequential reasoning skills as means to achieve expertise, it often neglects the development of sensory capacities, which appear to be essential for exceptional performance.

INTUITIONISM IN LOGIC AND MATHEMATICS

The term *intuitionism* derives from the 18th-century philosopher Immanuel Kant's account of temporal intuition as being a priori. Intuitionism considers mathematics purely the result of constructive mental activity and as having no principles relating to an objective reality. On this view, logic and mathematics are not activities that reveal any deep levels of reality but are simply the application of internal methods to build more complex mental constructs.

Intuitionism is characterized by its interpretation of what it means for a mathematical or logical statement to be true. In mathematical intuitionism, a mathematical statement corresponds to a mental construction, and a mathematician can only assert the truth of a statement by verifying its validity through intuition; that is, the truth of a statement is equivalent to the mathematician's being able to *intuit* the statement, something that does not of necessity relate to its provability. Communication between mathematicians serves only as a means to create the same mental processes in different minds.

A mathematical object is considered the product of a mind so that if it can be constructed then it exists. This entry first explains the foundations of intuitionism, its relation to the concepts of infinity and natural numbers, and continues with a history of intuitionism including the contributions of its key thinkers up to the present day. Following a section outlining the practice of intuitionistic logic, the entry concludes with a description of recent and current developments in the field.

Forms of Intuitionism

Intuitionism is a form of mathematical constructivism since it asserts that it is necessary to find (construct) a mathematical object to prove it exists. Put another way, to claim that an object with certain properties exists is to claim that an object with certain properties can be constructed. A mathematical object is considered a construct of the mind; therefore, its existence is equivalent to the possibility of its construction. This is in contrast with the classical approach, which tells us that existence of an entity can be proved by refuting its nonexistence. Intuitionism disputes this, stating that refuting an object's nonexistence does not prove that it is possible to find a construction for the apparently valid object, something that is required in order to assert its existence.

Time is an essential factor in dependent on the notion that statements can become provable in time and could therefore become intuitionistically valid where they were not so before.

Intuitionism and Infinity

The various forms of intuitionism feature differing positions on the meaning and reality of infinity. The term *potential infinity* refers to a mathematical procedure that has an unending series of steps. Once each step is completed there is always another step to be performed. The process of counting 1, 2, 3, and so on is an example. *Actual infinity* refers to a complete mathematical object that contains an infinite number of elements. The set of natural numbers $\{0, 1, 2, 3, 4, 5, \dots\}$ is an example.

According to the German mathematician Georg Cantor's set theory, there are many different infinite sets, and some are larger than others. For example, the set of all the real numbers, $\mathbb{R}$, is larger than $\mathbb{N}$, the set of all natural numbers, because all attempts to put natural numbers into one-to-one correspondence with real numbers will fail, and there will always be an infinite number of real numbers left over. Any infinite set that can be placed in one-to-one correspondence with the natural numbers is said to be *countable*, while infinite sets larger than this are said to be *uncountable*. This approach formed the foundations of mainstream mathematics.

Intuitionism set out to reject the reality of uncountable infinite sets. The Dutch mathematician L. E. J. Brouwer rejected the concept of *actual infinity* but accepted the idea of *potential infinity*. He claimed that there is no evidence to support the belief in the existential character of the totality of all natural numbers. The sequence of numbers that grows beyond any stage already reached by passing to the next number is a manifold of possibilities open toward infinity. While it remains forever in the status of creation it is not a closed realm of things existing in themselves. Brouwer insisted that mathematics in its classical form went beyond all human possibilities of realization and beyond statements that can claim meaning and truth founded on evidence.

Finitism

Finitism is an extreme form of intuitionism that rejects the idea of potential infinity. Finitism holds that mathematical objects cannot exist unless they can be constructed from the natural numbers in a finite number of steps. The Platonic idea of mathematical objects such as infinite sets being accepted as legitimate mathematical objects is rejected. Natural numbers are accepted as existing, but the set of all natural numbers is not considered to exist; therefore, discussion of infinite domains is not meaningful. In *The Philosophy of Set Theory*, Mary Tiles terms those who allow for *countably* infinite objects as *classical finitists* and those who disallow *countably* infinite objects as *strict finitists*. Leopold Kronecker was a famous finitist who believed that God created all the natural numbers, but everything else was a human creation.

The use of infinite objects has long been a controversial subject in mathematics. Brouwer rejected the existence of infinite objects until they are constructed. David Hilbert believed that finite mathematical objects are concrete objects and infinite mathematical objects are ideal objects. He believed it is possible to illustrate that any theorem about finite mathematical objects obtained using ideal infinite objects can also be obtained without them. Allowing that there are infinite mathematical objects does not cause a problem with finite objects.

Origins and History of Intuitionism

Intuitionism can be traced back to the mathematics of antiquity, then later to academics including Carl Gauss, Leopold Kronecker, Henri Poincaré, Henri Lebesgue, and Émile Borel. During the 19th century, discussions between German mathematicians Georg Cantor and his tutor Kronecker were instrumental to the development of intuitionism, later followed by Gottlob Frege and the critiques of his work by Bertrand Russell.

At the beginning of the 20th century, Brouwer advanced his comprehensive critique of classical mathematics, a program we now know as intuitionism. Brouwer systematically constructed the principal branches of intuitionist mathematics including set theory, mathematical analysis, geometry, and topology.

French philosopher Henri Bergson developed a version of intuitionism in his *Introduction to Metaphysics*, where he posited that an object can be known in two distinct ways, either *absolutely* or *relatively*. Knowledge is attainable relatively through analysis and absolutely through intuition. Bergson explains intuition using the analogy of a city. We can only grasp the dimensional value of a city by walking through it, we can never know it in the same way, even if we have photographs taken from every possible point of view. Similarly, the experience of reading a line of Homer: While we can translate the line and heap commentary upon it, our commentary can never grasp the simple dimensional value of experiencing the poem in its originality. Intuition, for Bergson, is the act of getting back to the things themselves.

Georg Cantor was the inventor of transfinite arithmetic, which was subsequently rejected by many esteemed mathematicians, including his tutor Kronecker—a confirmed finitist. Cantor's logical methods to prove his results in transfinite arithmetic are essentially the same as those later used by Russell in constructing his paradox. Cantor was responsible for the creation of the first version of set theory at the end of the 19th century as part of his study on infinite sets although it was Frege's attempts to reduce all mathematics to a logical formulation via set theory that led to Russell's paradox. Frege's axiomatic set theory was developed in response to early attempts at set

theory, with the goal of determining precisely what operations were allowed and when.

This was then derailed by Bertrand Russell who discovered Russell's paradox, demonstrating that one of Frege's rules of self-reference was self-contradictory. Russell discovered that naïve set theory contained a contradiction. It had been thought that for every concept there exists a set of things that fall under that concept. For example, corresponding to the set *feather* are all the feathers in the world. Even concepts such as *mermaid* are associated with sets, namely, the empty set. Russell pointed out, however, that there is no set corresponding to the set *not a member of itself*.

If there had been such a set—a set of all the sets that are not members of themselves—and we called this set *S*, then is *S* a member of itself?

If it is, then it is not (because all the sets in *S* are not members of themselves), and if *S* is not a member of itself, then it is (because all the sets not in *S* are members of themselves). Either way a contradiction ensues and therefore we can safely say that there is no such set as *S*.

Kronecker took the natural numbers as primitively generable and primitively graspable mental constructions that can subsequently construct other kinds of mathematical objects. Neither the natural numbers nor any other infinitely numerous objects of any kind can be thought of as comprising a completed totality as an object to be treated in its own right. Mathematical objects, since they are mental constructions, depend on their mode of construction, presentation, or description for their identity. They possess intentional identity conditions, which means that their identity relation is effectively decidable. By contrast, the extensional identity in mathematical objects is not generally decidable.

Stephen Kleene subsequently submitted a more rational account of intuitionism in his *Introduction to Meta-Mathematics* in 1952. Kleene helped to lay the foundations for theoretical computer science and was a founder of the branch of mathematical logic known as *recursion theory*.

Early in the 20th century, Brouwer gave the first formal exposition of intuitionism, when he set out his criticisms of certain conceptions in classical mathematics. He questioned the status of existence in mathematics, in terms of how we may

consider the established existence of an infinite set. Brouwer took the notion of natural number to arise out of our a priori conception of successive moments in time. In contrast with Platonism, which holds that mathematical concepts exist independent of any human realization of them, Brouwer held that only those mathematical concepts that can be demonstrated, or constructed, following a finite number of steps are legitimate. Unlike many other mathematicians, Brouwer was willing to abandon the vast realms of mathematics built on nonconstructive proofs.

Brouwer believed mathematics to be a language-less creation of the mind. For him, time is the only a priori notion as proposed by Kant. Brouwer distinguished two acts of intuitionism: The first act was to completely separate mathematics from mathematical language and from theoretical logic. Intuitionistic mathematics is an activity originating in the perception of a movement of time. This act gives rise to the natural numbers and restricts the kind of reasoning we may do, including that of the principle of the *excluded middle*. Brouwer's view differed from other constructive views in allowing for the construction of infinite sequences and that mathematics is the creation of a free mind, making it neither Platonic nor formal.

The second act is the creation of a *free choice sequence*. This is given by a constructing agent or creative subject who is free, at any stage of the progression of a sequence, to choose the next number in the sequence. For example, if someone is asked to produce a binary free choice sequence they might start "000. . .0" for a hundred digits then completely unexpectedly choose "1" as the next digit. A real number classically thought of as a converging sequence does not need to be given a determinate rule. It is only subject to a Cauchy restriction or a certain rate of convergence.

So, for Brouwer in intuitionism in mathematics the free creation of the human mind is at work, and objects only exist insofar as they can be mentally constituted. The natural numbers and the continuum are basic notions given to us directly by intuition. His intuitionistic theory of mathematics differs from that of others on the basis of the free choice sequence.

Criticism of the Excluded Middle

Brouwer criticized the law of the excluded middle. He became convinced that universal validity of contradiction proofs for existence proofs were unwarranted. This has significant implications for mathematics because it is performed on an everyday basis. To say "A or B" to an intuitionist is to claim that either "A or B" can be proved. The law of the excluded middle, that is to say "A or not A," cannot be allowed as a general inference rule.

The principle of the excluded middle asserts that for every proposition either that proposition is true or its negation is true. The excluded middle has its earliest formulation in Aristotle's principle of noncontradiction, wherein he states that of two contradictory propositions (where one proposition is the negation of the other) one must be true and the other false. The principle posits that it is impossible for there to be anything *between* the two parts of a contradiction. For example, where "P" proposes that

Socrates is mortal

then the "law of excluded middle" affirms that

Either Socrates is mortal, or it is not the case that Socrates is mortal.

The potential *middle* position (that Socrates is neither mortal nor nonmortal) is logically disallowed so that the first possibility whereby Socrates is mortal, or the negation of this possibility (it is not the case that Socrates is mortal) must be true.

An intuitionist would not accept this argument without further support for that statement since the proof is nonconstructivist. Negation as a concept has a different interpretation in intuitionist logic compared with classical logic. In classical logic negating, a statement involves asserting that a statement is false. An intuitionist on the other hand would take this as meaning that the statement is refutable, in other words, that there is a counterexample (a proof there is *no proof*). There appears then to be an asymmetry between positive and negative statements in intuitionism: for example, if statement P is provable, it is clearly impossible to prove that there is "no proof of P." However, even if we can show that no *disproof* of P is possible, we cannot conclude from its absence that there is a proof of P. P is thus a stronger

statement than not-not-P. To reiterate, just because there is no proof that there is “no proof of P,” we cannot conclude that there “is a proof of P.”

One way to think of this odd consequence of the law of the excluded middle is that when it is projected beyond the immediate circumstances of our ability to ascertain its truth by observation it becomes problematic. On this basis, intuitionists must reject it. Extrapolating the law of the excluded middle into the future or into the past brings with it difficulties. Our strong intuitive sense of realism means it doesn't make it feel strange to assert that something that hasn't happened yet either will happen or will not happen. There is no third possibility, so one of the propositions is true and the other false; just because they haven't happened yet does not make them false. This remains a problem for realists. However, the risk of taking this view is that we can end up in determinism. Assuming that all future contingents have an absolute truth implies they are set in stone and there is no freedom of choice, an orientation that many would reject.

As an example, take Goldbach's conjecture that every even number is the sum of two primes. As yet, no one has discovered either a proof or a counterexample. From a realist perspective, it makes sense to suppose that this conjecture might be true since every one of the infinite series of even numbers is a sum of two primes (although there may be no proof to be discovered).

For an intuitionist, the only thing that could make it true that all even numbers are the sum of two primes is that there is a *proof*. From the intuitionist point of view, there may be no proof and no counterexample and thus nothing to give the conjecture a truth-value.

Intuitionistic Logic

Mathematics requires intuitionistic logic, or *constructivist* logic, to preserve its justification, rather than truth. Intuitionistic logic, also known as *constructivist logic*, is the symbolic logical system developed by the Dutch mathematician Arend Heyting (1898–1980) aimed at providing a basis for Brouwer's program of intuitionism. Intuitionistic logic substitutes justification for truth in its logical calculus. The logical calculus is responsible for preserving justification rather than truth,

giving philosophical support to several schools of philosophy, notably Michael Dummett's *anti-realism*. Dummett was a highly influential philosopher who did not find Brouwer's interpretation of intuitionism convincing because it relies on the idea that a mathematical construction is a process carried out by an individual mathematician in the privacy of their own mind, hence seeming to identify the meaning that one individual attaches to a mathematical term with a private mental object, which only that person has access to.

The system preserves justification, rather than truth, across transformations yielding derived propositions. Practically, there is a good case for using intuitionistic logic, since it has the property of existence, which renders it suitable for use in other forms of mathematical constructivism. The syntax of formulae in intuitionistic logic is similar to that of propositional logic; however, its connectives are not interdefinable in the same way. In intuitionistic logic, it is possible to disprove many of the tautologies of classical logic. Examples include the law of the excluded middle, Peirce's law, and even double negation elimination. In classical logic, both and also are theorems. In intuitionistic logic, only the former is a theorem: Double negation can be introduced but cannot be eliminated. In observing that many classical valid tautologies are not theorems of intuitionistic logic, the proof theory of classical logic is weakened.

The question of how much structure sensory input has of itself and how much we give it through processing is one of the central problems of philosophy and in cognitive science in general. Intuitionism, unlike realism, holds that mathematical entities cannot exist independently of the human mind. Mathematics is not out there to *be discovered* but is rather constructed as an exercise in human intuition. Mathematical objects are created through mental activity.

Ongoing Development of Intuitionism

Although intuitionism has never replaced classical mathematics as the standard view, it has attracted much attention and continues to do so today. Philosophers and mathematicians alike were forced to acknowledge the lack of an epistemological and ontological basis of mathematics, even when their loyalties lay elsewhere. Even the likes of Kurt

Gödel, a lifelong Platonist, and Hermann Weyl, who later stopped practicing intuitionistic mathematics, continued to admire Brouwer's intuitionistic philosophy of mathematics.

In 1936, Alan Turing (1912–1954) considered nonconstructive systems of logic with which not all the steps in a proof are mechanical, some being intuitive. The Church–Turing thesis (also called *Church's thesis*) emerged from research in the foundations of logic and mathematics. The conjecture bears on what a computer ultimately can do (and thus what it cannot do). Later Stephen Cole Kleene brought forth a more rational consideration of intuitionism, where he stated that there are no paradoxes in Cantorian set theory—thereby calling into question the program of intuitionist mathematics.

In the late 1940s, a group of mathematical logicians headed by A. A. Markov undertook the task of developing a constructive mathematics, with a tendency close to that of mathematical intuitionism known as *recursive constructive mathematics* or *recursive function theory* (RUSS).

Bishop's constructive mathematics in *Foundations of Constructive Analysis* (1967) provided a constructive development of a significant part of 20th-century analysis. His mathematics (termed *BISH*), unlike intuitionistic or recursive constructive mathematics, admits of many interpretations. In fact, the results and proofs of BISH can be interpreted in most reasonable models of computable mathematics, for example, Klaus Weihrauch's type two effectivity theory and Andrej Bauer's model.

Fred Richman took logic as the primary characteristic of constructive mathematics. This was in contrast to the pioneers of constructivism Brouwer, Heyting, Markov, and Bishop who believed in the primacy of mathematics over logic. Richman saw constructive mathematics as characterized by its methodology based on the use of intuitionistic logic.

Per Martin-Löf's constructive type theory (ML) published in *Notes on Constructive Mathematics* (1968) is in the spirit of RUSS rather than BISH; it had the advantage of facilitating the extraction of programs from proofs. This led to work on the

implementation of constructive mathematics by Robert L. Constable; Susumu Hayashi and Hiroshi Nakano; and Helmut Schwichtenberg. Recent implementations of type theory for proof extraction include the programs Coq and Agda.

The field of mathematical intuitionism is still being intensively developed. The emphasis placed by intuitionists on the effectiveness of its results sits well with the computational tendency in modern mathematics and continues to draw many outstanding minds to its study.

J

JUSTIFICATION

Justification (J) is defined as the reason or set of reasons for which someone holds a belief. J focuses on the reasoning behind affirming a statement or proposition. J is a *rational defense* of an argument, as opposed to an *imposition* based in power, coercion, or the tradition of an argument. Entities that can be justified include from beliefs, values, emotions, or behavior to laws, judicial decision, or scientific theories. J is an account of why a statement can be considered as a true one. J is an explanation on how one knows what one knows. There is a sort of J addressed to justify statements, and there is a sort of J addressed to justify behavior. J can be based on fact (positive justifications), values (normative justifications), and inferences (logical justifications). Examples of J include trying to persuade others to share our own beliefs, convincing friends to buy one disc rather than another, defending our own words and actions against critics, and self-interested statements of politicians and advertisers.

J focuses on beliefs. As a general rule, theories of J focus on the J of beliefs. This is in some way due to the influence of the seminal conceptualization of knowledge as *justified true belief*. If a belief is justified, there is something that justifies it, which is often defined as a *justifier*. If a belief is justified, then it has at least one justifier. Examples of justifiers for a belief are observational statements or other justified belief. For example, if a person is aware that her dog returned from the

yard smelling like garbage and that the trashcan outside had fallen over, the stink and the trashcan can be evidence for her belief that her dog went through the garbage. In that case, the justifiers are the person's awareness of the stink and the trashcan, and the belief that is justified is her belief that her dog went through the garbage.

Theory of J

Theory of J can be defined as the attempt to understand the J of statements and beliefs. There are various stances on what requires a *good* J. The core question for most of the theories of J is how to be sure or what we need in order to know or to assert that our beliefs correspond to the actual world. Differences among theories of J depend on what types of sources or evidence is required before a belief can be considered justified.

Theories of J are related to several epistemic features of beliefs. These include four crucial ideas for the theory of J: J, warrant, rationality, and probability. If A makes a claim *x* and B then casts doubt on it, A's next step would usually be to offer a J for *x*. Criteria that are used to consider a J as valid are where the boundaries are plotted between different theories of J and their philosophical foundations. Much of the debate in this field is focused on analyzing the nature of knowledge and how it relates to interlinked concepts, such as belief, truth, and J.

One negative theory of J is nonjustificationism. Nonjustificationism is the thesis that it is not possible to properly assign truth-values to sentences.

This view is often attributed to the work of Hans Reichenbach (1891–1953) and to the oeuvre of Karl R. Popper (1902–1994). Reichenbach thought that there was no logic of scientific method—that is, no proof or refutation. The basis for his claim was that there could be no refutation, as any theory could be protected from a putative refutation with some ad hoc maneuver.

In a different view from Reichenbach's conception, Popper also developed a theory on the growth of scientific knowledge *without* J. His conception is not justificationist, in the extent to which it does not properly claim to assign truth-values to propositions. All statements are hypothetical. Rather than asserting that a singular statement is truthful, Popper asserts that a basic sentence may be only provisionally accepted, and only if, this sentence is testable. Then, Popper introduces the following rule: consider only basic statements. Provisional acceptance of basic sentences—Popper claims—does not disqualify them as refutations of theories because for the most part we can agree on which basic statements we provisionally assume to be veridical. Secondly, Popper proposes the following rule: One should always substitute any theory which is contradicted by a basic statement by whichever new alternative theory that has a higher degree of falsifiability.

There are several different views on what entails a J. The first has to do with the classical opposition between an a priori J and an a posteriori J. A second discussion is on internalist versus externalist conceptions of a J. Finally, a third relevant concern is on the debate between foundationalism and coherentism in the theory of J.

A Priori J Versus A Posteriori J

There has been a long philosophical debate between empiricism and rationalism on what a *good* J is. Roughly speaking, rationalists defend an a priori conception of J, whereas empiricists defend an a posteriori conception of J. Each of these positions has been defended by a number of scholars. The oeuvre of Albert Casullo represents a skeptical vision on rationalism, whereas the work of Laurence Bonjour defends the rationalists' approach. On the other hand, other scholars

have attempted to challenge the cogency and significance of the a priori/a posteriori distinction, arguing that some warrants or justifications are neither a priori nor a posteriori.

On this concern, rationalism's argument is the following. Consider any belief or judgment affirming that *m* is inferentially justified on the basis of some other belief *n*. In order to be justified in believing *m* by inference from *n*, it is necessary (1) that one have good reasons for believing *n* and (2) that one have good reasons for thinking that *if n then m* (or *if n then probably m*). However, since experience might offer no direct support for the latter condition, any J for it must be (wholly or partly) a priori. Therefore, no experience can, on its own, directly justify a belief.

In opposition to the rationalist argument, empiricism responds by supporting the claim that one could justify general principles by induction from a number of experiences. Any J for it must be a posteriori. If successful, this would show that the empiricist is not vulnerable to the a priori problem. An example of this thesis can be seen through the empiricist J of mathematical beliefs. In this way, the inductivists' claim that appeals to an a priori source of J is *unnecessary* for the J of elementary mathematical propositions, in light of the available inductive support. Consider, for instance, the classical example of attempt to justify $1 + 1 = 2$. Confirming instances of this level of generality might involve counting one object and other one object, and then counting and finding them to be two in number.

Contrarily, the a priori conception of J affirms that those instances support the generality *only if* certain background assumptions are in place. In other words, mathematical propositions depend not just on *counting*: These propositions also depend on mathematical or logical claims to the effect that, for instance, some quantities are equal or unequal to others. Therefore, the J of some elementary mathematical claims will have to rely upon claims that are themselves not justified via induction. For example, the background assumption behind the sum according to which objects are stable can only be justified by assuming that the background assumption is already true. If a mathematical proposition must be justified by appeal to other a priori propositions, then this is no longer an

entirely a posteriori J—or a purely inductivist J—of elementary mathematical statements.

Therefore, a subject that has an a posteriori J, it essentially depends on statement of particulars or property instances. The belief that the abstract notion of circle exists, for example, might be justified by one's awareness of particular circles. Contrarily, a subject has an a priori J if one's J or evidence for a belief does not depend essentially on any particulars but only on universals. For example, an assertion about abstract logical relation of exclusion or incompatibility between the attribute of being circular and the attribute of being rectangular can offer a J for judging that no circles are rectangular, as well as J for the inference from the statement that something is a circle to its not being a rectangle.

Internalism, Externalism, and J

Internalism and externalism are two opposing ways of explaining the conception of an epistemic J throughout different dimensions. There has been a long debate in philosophy among these approaches. This dispute addresses one of the most fundamental questions in the discipline; that is to say, what is the basic nature of epistemic J. It is usually held that a valid epistemic status is not an attribute of a simple fact. Rather, a valid epistemic status is a condition of a belief *X if and only if* belief *X* is justified, as a rule, in virtue of some additional obtained condition.

Within the context of epistemology, internalism is the thesis asserting that everything necessary to provide J for a belief must be immediately available to an agent's consciousness. Oppositely, externalism asserts that the justificatory status of a belief can depend on other factors than those internal to the epistemic agent holding that belief. Internalism (or mentalism) affirms that what ultimately justifies any belief is some mental state of the believer. On the contrary, externalism asserts the thesis according to which there is something different to mental states that function as justifiers.

To put it succinctly, externalism holds that there are entities in the world which justify our beliefs or determine our meanings. Therefore, externalism is the theory that the contents of at least some of one's mental states are dependent in

part on their relationship to the external world. Conversely, internalism asserts that a belief can be explained by pointing to things which are internal to the believer's mind.

The central idea behind internalism is related to the nature of the justifier of a given justified belief. The justifiers for a given justified belief are those matters that constitute the person's J for that belief. They are those matters on which the person's current J is based, such as other beliefs, experiences, or states of affairs. For instance, consider a person telling us that a bear was in the neighborhood yesterday, and suppose that the testimony you receive from another person produces in you the justified belief that a bear was in the neighborhood. We can say that a *justifier* for this belief is the testimony one has received from the other person.

Internalists hold a rule according to which one has J for believing *S* on the basis of *S'* *only if* one has a J for believing that *S'* makes *S* probable. A repeated criticism that externalists have posed to internalists is on the cost of the vicious regress that internalism has.

Foundationalism, Coherentism, and J

Foundationalism has to do with those theories of knowledge resting upon *justified beliefs*. The two main theses of foundationalism assert that (1) *basic beliefs* exist, which are justified without reference to other beliefs and (2) *nonbasic beliefs* must ultimately be justified by basic beliefs. Contrarily, coherentism does not require a foundation: A belief can be justified if this belief is a member of a coherent set of beliefs.

There are two versions of foundationalism: a strong (or classical) version and a weak (or moderate) version. Strong foundationalism holds that there are basic beliefs that serve as foundations to anchor the rest of our beliefs. It advocates the infallibility of those basic beliefs and the use of deductive reasoning between beliefs. Weak foundationalism accepts provisional basic beliefs, and the use of inductive analysis between them. To put it succinctly, strong versions of this theory affirm that a justified belief is completely justified by basic beliefs, whereas weak versions of foundationalism maintain that justified beliefs can be justified by basic beliefs but can be additionally justified by other justified beliefs.

Strong foundationalism takes immediate perceptions and direct experience as good items or as acceptable foundations for basic beliefs. The strong version of foundationalism holds that beliefs about those matters do not need further support to be justified. Basic beliefs can be justified by some specific attribute of the belief itself, such as its being self-evident. Contrarily, weak foundationalism does not entail that a basic belief is *self-evident*. In a different way, the weak version of foundationalism asserts that it is reasonable to assume that basic beliefs are justified unless confirmation to the contrary is present.

On the other hand, foundationalism can be internalist or externalist. Internalist foundationalists hold that basic beliefs are justified by mental events. In other words, internalism holds that it is necessary for the means of J of a belief to be accessible to the believer. Contrarily, externalist foundationalists don't require that a believer's J for a belief must be accessible to that for it to be justified.

Coherentism opposes foundationalism, characterizing epistemic J as an attribute of a belief *only if* that belief is a member of a coherent set. As a theory of J, coherentism restricts justified belief to that which coheres with some specified set of beliefs. Coherentists assert that not all plausible underpinning J for a justified belief is supported finally for a basic belief. A core idea of coherentism as a whole is that J is a function of some connection between beliefs, none of which are privileged beliefs. On the other hand, different types of coherentism differ among themselves by the specific kind of relationship among beliefs such that every type is considered as coherence.

Therefore, varieties of coherentism emerge from the meaning of the concept of coherence (i.e., what it means for a system of statements to be coherent). A strong definition of coherence holds that a system of statements must include logical consistency. A moderate conceptualization of coherence requires some level of integration of the constituents of the system of beliefs. On the other hand, a theory *C* that uses only one explanation for divergent phenomena is more coherent than a theory *D* that explains those divergent phenomena using unrelated explanations. Additionally, a system *A* that uses only one explanation is more coherent than a system *B* that contains more than one unrelated explanation for the same phenomenon. Finally, to the extent to which the number of

phenomena explained by the system is greater, the greater will be its coherence.

Coherentism also opposes foundationalism's response to the so-called *regress argument*. The regress argument can be synthesized in the following way. Given some assertion *S*, it is plausible to require a J for *S*. If that J takes the form of another statement—let's call this statement *S'*—it is again feasible in logical terms to ask for a J for *S'*, and so on. Foundationalism's solution holds that the series of the questioning process finishes with certain statements having to be self-justifying. Coherentism's solution maintains that the series of questioning process forms a circle, so that each statement is ultimately involved in its own J. A third approach, infinitism's solution, maintains that the series is inherently infinitely long, with every proposition requiring a J by some other proposition, and so forth.

Foundationalism holds that it is unnecessary to require a J of certain propositions because they are self-justifying. Contrarily, coherentism asserts that it is always necessary to require a J for any proposition. From the coherentism's point of view, foundationalism proposes an unjustified place to end asking for J. Coherentism also maintains that foundationalism does not provide plausible reasons to think that certain beliefs do not require J. Foundationalism responds that it seems unreasonable to ask for justifications to certain statements (e.g., observational statements) such as, for instance, "it is raining."

Thus, coherentism rejects the reliability of the regression argument. The regression argument asserts that the J for a statement takes the form of another statement (e.g., *S''* justifies *S'*, which in turn justifies *S*), making J a linear process that ends at some statement that does not ask for J, that is, a justified belief. For coherentism, J for the belief in *S* is nonlinear: J is a *systemic* process. This means that *S''*, *S'*, and *S* are components of a coherent set of statements. *S''* and *S'* are not prior to *S* in epistemic terms. Rather, coherentism holds that *S''*, *S'*, and *S* work in an integrated manner within a set of statements to attain J.

J and the Theory of Argumentation

J is a core concept in the theory of argumentation. An argument can be defined—at least in a preliminary manner—as a set of related propositions.

Roughly speaking, in the context of the theory of argumentation, a distinction can be established between broad conceptualizations and narrow conceptualizations of a J. A broad conceptualization includes several kinds of defenses for an argument that seeks to prove that an argument is true. A narrow conceptualization defines J as a specific sort of reasoning facing an argument—that is, a reasoning that *is not* a way of arriving at ideas but rather a way of testing ideas critically. It is concerned less with how people think than with how they share their ideas and thoughts in situations that raise the question of whether those ideas are worth sharing. Thus, the question becomes the standards by which arguments succeed or fail to provide J for claims.

In terms of the *ends* orienting a J, there are two main types of J for an argument: strategic J and logical J. A strategic J of an argument pursues changing the belief of another person with relative or total independence regarding what is true—or perceived as true—by the speaker or writer. In turn, strategic J of an argument typically includes two different subtypes: (1) authoritative-based J of an argument and (2) emotional-based J of an argument. Contrarily to strategic J, logical J focuses on the plausibility of inferences and evidence to prove an argument. The logical J of an argument often uses syllogisms that include a major premise, a minor premise, and a conclusion based on the combination of the two premises.

Authoritative-based J of an argument appeals to the speaker's credibility, and establishing it depends less on their expertise and more on how they are depicted by themselves. To use credibility in favor of an argument, the speaker (or writer) must position themselves as an expert. Aristotle—the first to suggest an authoritative-based J of an argument that he called *ethos*—recommended that a speaker should use *powerful gesture, eye contact*, and so on “to position yourself as a leader.” Emotional-based J of an argument seeks to appeal to the emotions of the listeners, aiming to tempt them arouse their interest. An effective way of provoking passions is in appeal to values. Aristotle was also first to realize that language has a significant effect on emotion, and that certain words (such as fire, child, honor, or anger) can trigger senses and feelings. He called this kind of J for an argument, *pathos*.

Logical J of an argument—or *warrant*—is defined as a statement *authorizing the movement* from the *data* to the *claim*, using the terms of Stephen Toulmin. In his seminal approach to the theory of argumentation, a claim is a conclusion whose merit must be established. The classic Toulminian example of a claim is the following: If a person tries to convince a listener that he is a British citizen, the claim would be (1) “I am a British citizen.” Data or evidence is a fact one appeals to as a foundation for the claim. In that same example, the person introduced in (1) can support his claim with the supporting data (2) “I was born in Bermuda.” In order to move from the data established in (2), “I was born in Bermuda,” to the claim in (1), “I am a British citizen,” the person must supply a warrant to bridge the gap between (1) and (2) with the statement (3) “A man born in Bermuda will legally be a British citizen.” These aspects will be considered as a good argument *if and only if* they can succeed in providing good J to a claim, which will stand up to criticism and earn a favorable verdict.

The Toulminian model of argumentation includes three other related concepts: *backing*, *rebuttal*, and *qualifier*. A backing must be introduced when the warrant itself is not convincing enough to the readers or the listeners. In the seminal example given above, if the listener does not deem the warrant—or J—in (3) as credible, the speaker will supply the legal provisions as backing statement to show that it is true that “A man born in Bermuda will legally be a British citizen.” A rebuttal is a statement recognizing the restrictions to which the claim may legitimately be applied. The rebuttal, in the aforementioned example, is exemplified as follows: (4) “A man born in Bermuda will legally be a British citizen, unless he has betrayed Britain and has become a spy of another country.” Finally, a qualifier is a word or phrase expressing the speaker's degree of force or certainty concerning the claim. Such *words* or phrases include “probably,” “possible,” “impossible,” “certainly,” “presumably,” “as far as the evidence goes,” or “necessarily.” The claim (5) “I am definitely a British citizen” has a greater degree of force than the claim (6) “I am a British citizen, presumably.”

The work of Carl R. Rogers and his disciples introduces what might be considered a third type of J for an argument: a deliberative-based J. This type of J can be separated into five components: (1) an

introduction to the problem and a demonstration that the opponent's position is understood; (2) a statement of the contexts in which the opponent's position may be valid; (3) a statement of the speaker's position, including the contexts in which it is valid; (4) a statement of how the opponent's position would benefit if he were to adopt elements of the speaker's position; and (5) if the speaker can show that the positions complement each other, that each supplies what the other lacks, so much the better.

K

KINETIC (MOLECULAR) THEORY

The kinetic theory of an ideal gas establishes a connection between mechanics and thermodynamics, suggesting that thermodynamic quantities can be understood in terms of mechanical properties averaged over a population of particles. An ideal gas is one of the simplest models for a physical system consisting of multiple particles and is an excellent approximation to many real gases. Moreover, as this entry shows, even this very simple model introduces some long-standing conceptual issues in statistical physics, such as the nature of assumptions concerning randomness and the need for a discrete set of states a system can occupy.

Connecting Mechanics and Thermodynamics

In the early 19th century, the basic Newtonian mechanics of objects was well understood and could plausibly have been thought to be the fundamental physics underlying how the universe worked. The industrial revolution, however, prompted the invention of thermodynamics to handle systems considerably more complex than those captured by simple mechanical models. The working fluid of a steam engine can be described in terms of variables such as its pressure P , volume V , absolute temperature T , and entropy S . Some of these variables can be straightforwardly connected to basic mechanics: $P = FL/A$, or the

pressure is the perpendicular component of a force uniformly distributed over an area A . Steam somehow pushes against the walls of its container. But other variables, such as temperature, had no such translation into mechanics.

Consider the equation of state of an ideal gas, $PV = nRT$, where R is a constant and n , the number of moles, is a measure of the amount of gas. This equation combines variables that can be linked to mechanics and those that do not have an obvious connection. Now, thermodynamics can certainly be formulated as a stand-alone theory, without any grounding in basic mechanics. However, relationships like the equation of state suggest that there might be a connection. Indeed, physicists can seek to *reduce* thermodynamics to a more fundamental mechanical theory, providing a more unified description of nature and a deeper understanding of why thermodynamics works as it does.

Physicists perform this reduction through *statistical mechanics*: Thermodynamics becomes a description of systems with very large numbers of components. Thermodynamic variables are rooted in the average properties of a population of components. They are statistical variables.

The ideal gas equation of state might then be understood as describing the population of an immense number of particles. The volume V , for example, would then be the volume occupied by the whole population of particles, rather than the volume of any single particle. The pressure P would be due to lots of particles constantly bouncing off the walls of the container, and n would have to do

with the number of particles—all statistical, population-level descriptions. This leaves temperature to be figured out. In any case, the very basic statistical mechanics represented by the kinetic theory of an ideal gas requires an atomic theory of matter to be correct. Instead of being an infinitely divisible continuum, the ideal gas has to consist of a discrete, countable number of particles. The microscopic behavior of each individual particle will be captured by basic mechanics, and the statistical behavior of the population as a whole should reproduce the results of a thermodynamic analysis.

The ideal gas is one of the simplest possible models of a multi-particle system. Gas molecules very weakly interact with one another; in an ideal gas model, the particles do not interact with each other at all, undergoing completely elastic collisions with the walls of the container. With these assumptions, the kinetic theory calculation is very straightforward.

Say the container is a cube with each side having length L . Focusing on a single particle bouncing off only one of the six walls, each collision will result in a momentum change of magnitude $\Delta p_x = mv_x - (-mv_x) = 2mv_x$, where m is the mass of the particle and v_x is the x -component of its velocity. The particle will then travel to the opposite wall, bounce off that, and make its way back for another collision. The time interval between each collision is then $\Delta t = 2L/v_x$. Since force is the rate of change of momentum, the time-average of the force delivered to this one wall by one particle must be $F_x = \Delta p_x / \Delta t = mv_x^2 / L$.

Now, the total force will be $\Sigma F_x = Nm\overline{v_x^2} / L$, where N is the number of particles and $\overline{v_x^2}$ is the average of the square of the x -component of the velocities of the particles. The pressure is this force divided by the area of one side, L^2 . Therefore $P = \Sigma F_x / L^2 = Nm\overline{v_x^2} / L^2$. The volume of the container is L^3 , and $Nm\overline{v_x^2}$ looks like it is related to the total kinetic energy, $K = 1/2 Nm (\overline{v_x^2} + \overline{v_y^2} + \overline{v_z^2})$. But there is no distinction between the x , y , and z directions, and therefore $\overline{v_x^2} = \overline{v_y^2} = \overline{v_z^2}$. Putting all this together, the result is $PV = 2/3K$.

The ideal gas equation of state, established through empirical means with actual gases, is

$PV = NkT$, now phrased in terms of the number of particles and the Boltzmann constant k , such that $nR = Nk$. All this means that in an ideal gas, temperature must be related to the total kinetic energy of the population of particles so that $K = 3/2NkT$. Alternatively, the temperature of an ideal gas tells us that the average kinetic energy of the particles is $\overline{K} = K/N = 3/2kT$.

This result of kinetic theory, linking microscopic mechanics with macroscopic thermodynamics, applies to the ideal gas only. Physicists would later establish a more general definition of temperature in terms of how entropy changes as the total energy U of a system increases; $1/T = \partial S / \partial U$. In statistical mechanics, entropy is related to the number of microscopic states that produces the same set of macroscopic thermodynamic variables that define a system. For an ideal gas, however, the only energy in the system is kinetic energy, and it is possible to establish the mechanical meaning of temperature without dealing with the complexities of entropy.

The kinetic theory of an ideal gas, therefore, is just a first step in reducing thermodynamics to statistical mechanics. The connection kinetic theory establishes between temperature and kinetic energy in a gas, however, is highly significant: with a very simple, exactly solvable model, it shows that a connection can be made. Indeed, the stripped-down, simplified nature of an ideal gas model helps emphasize the fundamental features of a statistical approach to large many-particle systems. Complications can be built in later. Moreover, an ideal gas is an excellent approximation to most gases under everyday conditions, so much that engineers typically take the gases they work with to be ideal gases under most circumstances.

Conceptual Issues

While kinetic theory can be thought of as an early, and still useful, application of statistical mechanics, the vastly simplified model of an ideal gas also leads into some of the conceptual issues that a more mature statistical physics has to confront. The most prominent of these issues are the nature of the randomness assumptions in statistical models, the meaning of probabilities in the models, and the necessity of discrete state spaces for well-defined concepts.

Randomness and Probability in the Ideal Gas

Since basic kinetic theory refers to averages in a population of particles, questions about how the positions and velocities in an ideal gas are distributed arise. In a more developed statistical mechanics, the velocities have the well-known Maxwell–Boltzmann distribution. The positions of the particles are random, uniformly distributed throughout the volume. But all this is not part of kinetic theory. Indeed, there is a question of why randomness should appear in the initial conditions.

One possible answer is that if all initial positions for the ideal gas particles are equally likely, the probability for anything but a random initial distribution is exactly zero. If, for example, the particles in an ideal gas started arranged on a cubic lattice, with identical velocities, such a configuration might produce odd results such as unequal pressures on the container walls. However, not only this, but any ordered arrangement has zero probability.

Statistical physics then proceeds beyond kinetic theory by introducing the fundamental assumption that all microscopic states of the population of particles, constrained by appropriate requirements such as equal total energies, must be equally probable. Such an assumption can be hard to justify beyond the fact that it works, since the Newtonian mechanics that is supposed to underlie thermodynamics is completely deterministic.

The probabilities that are fundamental to statistical physics raise similar questions. For example, entropy can be defined through the information entropy as $S = -k \sum p_i \ln p_i$, which refers to the probabilities p_i of physical states. Indeed, so defined, entropy measures a lack of information about the state of a system. But there is something peculiar about such a perspective. After all, the thermodynamic definition of entropy has $\Delta S = dQ/T$, a quantity related to heat transfers that can be measured in a lab through calorimetry. Does entropy say something about the lack of knowledge of a physicist—are the p_i epistemic probabilities? Or are the probabilities, like the thermodynamic entropy, objective features of physical systems, independent of the physicist?

One approach to supporting the fundamental assumption is ergodic theory, which studies whether the states occupied by a population of particles evolving in time are a representative sample of all the states assumed to be equally probable. Many dynamical systems, although deterministic, are sensitive to initial conditions in a manner that means that any uncertainty in the knowledge of the state of a system grows exponentially with time. In effect, the systems become randomized. If ideal gas particles are allowed to collide with each other or if the walls of the container have irregularities, the result will be a similar degradation of knowledge about the precise state of the system—there will be no alternative but to describe the gas by using macroscopic, statistical variables.

Processes that lead to loss of information can bridge the gap between deterministic mechanics and assumptions of randomness, and the gap between epistemic and objective probabilities. Nevertheless, not all details are clear, and such conceptual issues have continued to interest both statistical physicists and philosophers of science.

The Need for Discrete State Spaces

Kinetic theory connects thermodynamics and particle mechanics by discretizing the ideal gas: taking the gas to be a countable collection of particles. Another conceptual problem that arises at this stage comes from the fact that the process of discretization is incomplete: The classical ideal gas still has a continuous, nondiscrete state space. This leads to infinities and other difficulties that require quantized states for their resolution, hinting at a deeper connection between statistical and quantum physics.

The entropy of a system is defined in terms of the information entropy or, equivalently, in terms of the number of microscopic states corresponding to macroscopic thermodynamic states. The states of the classical particles that make up an ideal gas are defined by the particle position and momentum. But both the position and momentum are continuous variables. Therefore, there are an uncountable number of states of an ideal gas, and defining an entropy through state-counting becomes impossible.

In the late 19th and early 20th centuries, thermodynamic theories ran into some notorious problems with infinities, such as the “ultraviolet catastrophe” and the divergence of specific heats due to the equipartition theorem. In hindsight, these were evidence of the need for quantum mechanics. Early workarounds for these problems recognized that discretizing the state space led to finite results that could fit observations.

An early attempt to discretize the state space of an ideal gas produced the Sackur–Tetrode equation for the ideal gas entropy, which works very well at temperatures where the ideal gas particles behave classically. The discretization is, however, somewhat crude, and at temperatures close to zero, the Sackur–Tetrode entropy becomes negative, which is absurd.

A more proper quantum treatment of an ideal gas uses the wave functions for particles confined to a box. While the wave functions and the energy levels in this case are exact solutions, obtaining most quantities of interest in statistical mechanics requires the partition function, which is not exactly summable. The quantum ideal gas might be the modern equivalent of kinetic theory, but it relies on high-temperature approximations and numerical calculations to produce results. Unlike the easily visualizable, mathematically tractable model of the kinetic theory of a classical ideal gas, even the simplest possible quantum multiparticle system analogous to an ideal gas requires more advanced techniques and is not very intuitive.

KNOWLEDGE

Theories of knowledge serve as a foundation logic for schools of thought about human experience and the world. Schools of thought can be distinguished by their varied beliefs about how knowledge is defined, how it is acquired, the differences among cognitive states involved, and how it is represented. There is a great benefit to reducing vast amounts of discrete information, or experience, to form broad generalizations that help filter the continuous barrage of new perceptions. Persons unable to impose such filters on their experience become overwhelmed, as seen in some autistic people who panic and adopt insulating behaviors to limit the scale and intensity of stimulation and the ambiguity of sensation and experience. Thus there is a high value placed on knowledge that is consistent within a cohesive framework, resulting in worldviews that can allow new information to be assimilated and can expose fallacy while maintaining a sense of order. This entry discusses the nature of knowledge generally, including the distinction between knowledge and belief. It provides a brief overview of western historical notions of what constitutes knowledge, from ancient Greece through the medieval period, Cartesian mind–body dualism, the scientific revolution, the development of positivism and modernity. The entry concludes with a description of the more recent contributions of cognitive theory, developmental psychology, and other fields, and the connections of knowledge theory with other areas of investigation such as ethics, as well as information theory in the age of Big Data.

Defining Knowledge

In common usage, *knowledge* is an unambiguous term that indicates a framework for understanding information. Whereas information may be regarded as passive data, once it is understood in meaningful context, it contributes to a knowledge base. That knowledge base can then be applied to problems, in which case it becomes a tool for critical thinking. A knowledge base is foundational,

but it is not considered finite because doubts and curiosity persist to inspire further investigation. This is implied when an argument is qualified by the speaker's admission that it is "to the best of my knowledge." Thus the root of the word reveals its core attribute: the activity of knowing. Knowledge is thus assumed to be within the scope of human endeavors. It is further regarded as a continuous effort as people find order and meaning in their existence. The accusation that "you don't know what you are talking about" suggests not knowing enough information or not integrating it logically. That may be as nuanced a description of knowledge as most people care to use, but a much closer examination of knowledge by its nature and role in human experience is a primary focus of philosophical inquiry, broadly termed *epistemology*, variously defined as theories the nature of knowledge or the nature of knowing (see the entry on Understanding, this encyclopedia).

Knowledge is rendered ambiguous due to its several dimensions as revealed by responses to the following questions: What is the source of the knowledge—for example, innate, divine inspiration, authority, social convention, deductive reasoning, scientific observation? How robust is the knowledge? Is it absolute and eternal or relative and fluid? How is the knowledge organized, by isolated propositions or integrated frameworks? *Epistemic cognition* refers to the understanding one has about the nature of knowledge and learning. A causal chain typically considers the quality of information, the neutrality of reasoning, the degree of honest intention, and the influence of other factors, resulting in a familiar list of virtues associated with intellectual integrity: honesty, rationality, reliability, trustworthiness, and transparency.

The Nature of Knowledge

The Greek base word *episteme* (γνῶσις) means *to stand up*, for knowledge was assumed to be stable and therefore reliable no matter how it was acquired because the world to be known was assumed to be stable. Classical education focused on perennial laws and principles. The certainty with which these concepts were regarded as

universal corresponded to the authority granted to the source of this knowledge. The classical definition of knowledge requires three conditions: It must be believed, it must be true, and it must be justified, that is, *justified true belief*. Beliefs, or *doxo* (δόξα), are regarded as opinion, not fact, and are therefore changeable and subject to influence. In contrast, knowledge is expected to stand up to distortion and challenge. Justification constitutes the rational explanation and evidence that establishes the statement of knowledge, thereby providing an argument for its stability. The justification distinguishes knowledge from understanding; for example, Galileo's logical conclusions concerning astronomy, based on observation, were not accepted as knowledge until Johannes Kepler provided a supporting theory and mathematical explanation. By contrast, naive or intuitive understanding lacks explicit explanation, although there is lively debate on this point among philosophers. Some insist that knowledge can be a collection of separate facts, whereas understanding requires incorporation of knowledge into a cohesive framework.

The syllogism is the tool of classical analysis, examining phenomena in terms of the necessary and sufficient conditions specified in an authoritative definition of the concept. Implied here is that it is useful to define essential characteristics in order to make sense of the world, and further implied is that philosophical inquiry serves a broader purpose of trying to predict what may occur or explain why something has occurred. This view is called *positivist* because it assumes that one can be positive about the reality one hopes to know. In contrast, postmodern theories argue that the nature of the world is complex and changing and therefore knowledge cannot be any more stable than the world it describes. Here the emphasis is more existential; that is, that knowledge is a conceit shared among people who have found similar meanings in their experiences. A postmodern departure from the assumption that universal truths can be identified and then used to make sense of novel situations is found in critical theorists such as Michel Foucault (1926–1984), who argued that no truth exists outside of the individual's context and cultural

interpretation, thus knowledge cannot be agreed upon, let alone generalized, because of the unique combinations of experience.

Acquiring Knowledge

The stability of reality is a different issue from the stability of knowledge. In ancient Greece, Plato's idealism and Aristotle's realism diverged regarding the nature of the world and the ways it may be understood, contrasting the mind with the body for apprehending truth. The *sensible*, which can be perceived directly from immediate, concrete, sensory experience, is qualitatively different from the *intelligible*, which can be understood indirectly through abstract thought. Plato dismissed sensation, which he thought could only result in opinion, not knowledge. Socrates, his teacher, sought to discover the essence of a concept, not a catalogue of its examples nor even the variations in context that would cause doubt. In Plato's Socratic dialogue the *Meno*, the student becomes knowledgeable by touring his existing, or foundational, understanding and drawing rational conclusions about the only dimension that existed for his teacher: abstract ideas that do not rely on a physical manifestation. The abstract concept was regarded as the knowledge base. The legacy of Plato can be seen in modern thinkers, beginning with René Descartes' (1596–1650) skepticism, Carl Gustav Jung's (1875–1961) theory of archetypes, and, more recently, the work of linguist Noam Chomsky, all of whom argued in various ways that certain concepts are innate, that is, a priori. Immanuel Kant (1724–1804) had introduced a transcendental idealist argument in hopes of resolving the mind–body issue, but his solution has not been universally accepted and the debate continues over the nature of mind and the relative position of the mental and material domains in the development of knowledge.

A large part of Aristotle's legacy is *empiricism*: the scientific tradition of perceiving multiple instances and reducing the data to a central tendency in order to propose or test a theory about some property of reality. Instead of assuming inherent universal concepts that are innately known by all people, this approach requires experience in order to discover essential characteristics.

The English philosopher John Locke (1632–1704) concurred, arguing further that we are not born with innate concepts but rather that the mind is a *tabula rasa*, or blank slate awaiting personal experience. Differences among the types of knowledge to be acquired are significant to education; that is, society's intentional efforts to expand the competence of the untutored. In 1859, the biologist and philosopher Herbert Spencer (1820–1903) argued for science to be included in the public school curriculum in his influential essay "What Knowledge Is of Most Worth." He challenged the traditional focus of education on classical analyses of universal concepts memorized by rote in favor of self-evident truths with relevance to students' personal lives. John Dewey (1859–1952), one of the most influential of American philosophers and educators, objected to false dichotomies that would mutually isolate functions of the mind and body. The educational implication was that knowledge could not simply be transmitted in the traditional way of lecture and memorization, but that authentic experience in a meaningful context is required in order to confront a misconception or lack of knowledge and thereby construct a new understanding. Folk wisdom accepts intuitive insight as a source of knowledge.

An interactive theory of knowledge is found in developmental psychology, as in the pioneering psychoanalyst Sigmund Freud's (1856–1939) model that describes not just an innate and predictable sequence of development but distortions of understanding resulting in abnormal behavior. Swiss developmental psychologist Jean Piaget (1896–1980) observed that children begin with concrete interaction with physical objects, or interobjectivity, and develop gradually more abstract reasoning. Lev Vygotsky (1896–1934), an influential Russian psychologist, emphasized intersubjectivity, that is, interaction with people, and current thinking respects the influence of context and self-image on an individual's capacity and tendencies to learn. In the parlance of cognitive psychology, a distinction is made between automatic versus controlled thought processes which have been associated with different neurological locations. The executive functions, controlled by the prefrontal cortex, include tools for knowing: vocabulary and working memory.

Representing Knowledge

Current tradition among educators divides experience into three realms: cognitive (thinking), affective (feeling), and physical (doing). These categories are useful for analyzing multiple dimensions of the same experience, resulting in different sets of knowledge. *Ontology* is the study of classifying knowledge. The medieval theologian Thomas Aquinas (1225–1274) sorted all knowledge on the basis of its need for matter and motion in order to be known. The American psychologist Howard Gardner has suggested multiple ways of knowing, or Multiple Intelligences, with which to experience the world and to represent one's knowledge of the world. This theory posits that any concept can be understood and represented in multiple ways, thus supporting education reforms that insist all children can learn if the instruction can be appropriately differentiated and delivered in an engaging way. This extends Jerome Bruner's (1915–2016) hypothesis that any knowledge can be learned if reduced to a developmentally appropriate conceptual unit, but it begs the question of how to determine whether the academic objective was achieved.

Interpreting evidence of learning is in the realm of educational assessment, which highlights the complexity of knowledge. The concern for valid assessment prompted a group of evaluators to develop a taxonomy of cognition, popularly named for the leader of the team, Benjamin Bloom (1913–1999). The original *Bloom's Taxonomy* identified the lowest level of cognition as *knowledge*, meaning simple facts with the next level as broader categories for grouping the knowledge, or *comprehension*. These two levels plus an *application*, which can transfer a concept to a new situation, constituted the lower levels of thinking and the foundational knowledge base necessary for the higher levels of thinking: *Analysis* involves sorting aspects of a complex body into different components and understanding how they work together; *synthesis* involves connecting concepts from different entities in order to create something new; *evaluation* involves making decisions and exercising judgment. Half a century later, a revision was published that refined the taxonomy, first of all by renaming the levels in language suggesting

the active function of thinking: (1) recalling, (2) explaining, (3) applying, (4) analyzing, (5) judging, and (6) creating. More significantly, the term *knowledge* was changed from designating the lowest level of cognition, into four dimensions that infuse all levels of thinking: factual, conceptual, procedural, and metacognitive. These are ontological divisions, that is, ways to sort knowledge according to its own characteristics; each of them is further articulated:

Factual knowledge includes knowledge of terminology (currently called *academic language* according to teacher certification standards), and knowledge of specific details and elements. This is the easiest category of knowledge to gather and to assess, for it tends to have *one right answer*, and is thus often tested with selected response items (e.g., multiple choice; true or false) which involve the lowest level of cognition, recall. *Conceptual knowledge* includes knowledge classifications and categories, or principles and generalizations; and theories, models, and structures that can thus group factual details by concept. Constructed, or extended, response items (e.g., essays, diagrams) can demonstrate conceptual understanding, typically requiring facts as illustration and deductive reasoning for justification. Mathematics and sensory perception offer the greatest certainty, which diminishes as the source of information recedes from matter and motion. Memory and that which cannot be observed directly are less certain. Abstract, philosophical issues are the most dubious as well as the most difficult to explain but are nonetheless valued for providing a stable worldview regarding one's purpose or, for many, the existence of a supreme being without the burden of scientific proof. Factual and conceptual knowledge are considered propositional, that is, they are statements of truth about the world beyond the individual's personal or procedural knowledge.

Procedural knowledge involves the practical application of factual and conceptual knowledge, using subject-specific skills and procedures, methods, and techniques as well as knowledge of criteria for deciding when to use them. Performance assessments, or demonstrations, are needed to assess procedural knowledge; mastery of attendant facts and concepts cannot be mistaken for procedural competence. For instance, knowledge of the

vocabulary specific to cooking and knowledge of the concepts of heat and seasoning are necessary but insufficient for knowledge of how to make dinner.

The final dimension, *metacognitive knowledge*, includes knowledge of strategies for learning and of cognitive tasks as well as knowledge of one's own self in terms of strengths and weaknesses in understanding. As the ancient philosopher Laozi (Lao Tsu) said: Knowledge of others is intelligence; knowledge of oneself is true wisdom. Metacognition serves the purpose of critical rationalism by reserving doubt for any pronouncement and by acknowledging a need for further inquiry. While self-knowledge was valued in order to "Know thyself," and "an unexamined life is not worth living," John Locke suggested that "internal sense" was not just a way to process external sensation, but a source of original ideas. Cognitive psychologies focus on the importance of self-awareness and their therapies center on dissonance between belief and experience, that is, knowledge. Canadian American psychologist Albert Bandura (1925–) contributed the concept of *self-efficacy*; that is, confidence in one's capacity to succeed. Another predictor of success is *epistemic cognition*; that is, understanding the nature of knowledge itself. This includes epistemic aims, such as the degree to which one wants to understand something, and epistemic values. The primary tool of metacognition is reflection, the deliberate exercise of self-awareness, valued highly by Socrates, who reputedly said "An unexamined life is not worth living." Reflection can be seen in *cybernetics*, a model for thinking systemically that focuses on feedback loops as the deliberate invitation of information that may not conform to one's assumptions of what is. This includes a political dimension, for consulting stakeholders is regarded as essential for effective implementation of any reforms. Metacognition can be seen in community-wide awareness of the variance of perspective within its collective consciousness.

Knowledge in Context

Specialized fields of knowledge have emerged, such as psychology, education, and law, each of which has its own philosophical traditions within its scope of interest. *Knowledge management* is

the study of information technology and the role of people who must store and analyze data. Peter Drucker (1909–2005), a business analyst, who coined the term *knowledge worker*, noting the change in economic context from farm to factory and now to information. *Truth in advertising* focuses on the expectation that any information provided be verifiably true; ambiguity and omissions are considered as reprehensible as falsification. Journalistic integrity prohibits plagiarism, for which careers are terminated. Intellectual property rights continue to be debated in the context of democratic *need to know* and scientific verification requirements.

Ethical concerns pervade the topic of knowledge, both its presentation and access to it. First-world citizens democratically demand that they have a need and a right to know, and there are common standards regarding the selective, distorted, or even deliberate misplacement of that which is true. Horace Mann (1796–1859), pioneer of professional teaching, called education "the great equalizer," a nod to the old saying that "Knowledge is power." Brazilian reformer Paolo Freire (1921–1997) proposed a *pedagogy of the oppressed* to challenge traditional exclusion of impoverished children from active engagement in learning. Academic standards and how they may be measured are major political issues because most formal schooling is funded publicly and accounts for a large part of state budgets; school reform may be presented as consumer protection legislation, thus equating knowledge with a commodity. Current educational reform has promoted the adoption of standards to define the knowledge base desired upon graduation, with Common Core standards of literacy and numeracy and Next Generation Science Standards gathering national momentum.

The recent expansion of computing capacity has resulted in massive amounts of data that can be analyzed with increasingly sophisticated statistical software, leading to a phenomenon undermining the traditional scientific model of testing hypotheses and generating theory. These theories are used to summarize principles thought to help explain phenomena in the real world, guiding future actions to influence that world. However, search engines such as used by Google now employ algorithms that identify ads compatible

with the user, having no conception of the meaning in those ads. This can render the usefulness of a theory moot because the validity of the data analysis inspires belief in the findings even without arguing philosophical merit. Thus knowledge for narrow epistemic aims may be justified without meaningfulness to other aims, such as reliable propositions of truth that can be generalized to other contexts. *Gettier cases* are scenarios contrived to illustrate unjustified true beliefs.

LAWS, SCIENTIFIC

Scientific laws are central to science, but what *is* a scientific law? It is quite easy to give some examples: Coulomb’s law of electrostatic attraction, Snell’s law of refraction, the Schrödinger equation for the evolution of a quantum-mechanical system. But what do these things have in common in virtue of which they get to count as scientific laws? What *is* a scientific law—in other words, an approximation of a law of nature? While this is primarily a philosophical question, it should be no less interesting to scientists and students of science than, say, the foundations of quantum mechanics. Of course, there are many scientists to whom the latter is of no interest: the “shut up and calculate” types. But if one is not content with merely using science as a tool and would like to go further and investigate what science says the world is really like, then one should find something of interest in our philosophical question: “What is a scientific law?”

Simple Regularity View

To get a sense of why the question “what is a scientific law?” is puzzling, it will help to consider a very simple answer first. According to the *simple*

Acknowledgment: This work has received funding from the European Research Council (ERC) under the European Union’s Horizon 2020 research and innovation program as part of the MetaScience project, Grant Agreement No. 771509.

regularity view, laws of nature, or scientific laws, are true generalizations, roughly of the form “all Fs are Gs,” in other words *regularities* in nature. A generalization of the form “all Fs are Gs” is *true* if, and only if, there are no Fs that are not Gs.

The following are thus some candidates for lawhood:

List 1

- All swans are white
- All marsupials have a pouch
- All philosophers like coffee

There are black swans in Australia, the short-tailed opossum is a marsupial that does not have a pouch, and (apparently) some philosophers do not like coffee. So, none of the examples in List 1 are laws according to the simple regularity view because they have exceptions and hence are not true.

Now consider:

List 2

- Everything travels at or below light speed
- All massive objects exert a gravitational force on all other massive objects
- All uranium spheres are less than 1 mile in diameter

The examples in List 2 are true generalizations; they hold at all times and places in the universe without exception. So, according to the simple

regularity view, all the examples on List 2 are laws of science.

So far, so good for simple regularity view; it provides a simple answer to our question “What is a law of science?”—namely, to be a law is to be a true generalization, and it seems to appropriately classify our examples; plausibly, it is not a law that all philosophers like coffee but it is a law that everything travels at or below light speed.

But now consider the following: “All gold spheres are less than 1 mile in diameter.” It is certainly the case that no gold sphere greater than 1 mile in diameter has ever been discovered. Let’s assume, then, that there really are no gold spheres greater than 1 mile in diameter (there never have been and never will be). That is to say, “All gold spheres are less than 1 mile in diameter” holds at all times and places throughout the universe; it is a *true generalization*. According to the simple regularity view, it is then a *law of nature* that all gold spheres are less than 1 mile in diameter.

Although we may be happy to admit that it is a law that all *uranium* spheres are less than 1 mile in diameter, we probably do not want to say that it is a law that all *gold* spheres are less than 1 mile in diameter. The former has to do with the fact that uranium is an unstable *radioactive* element, whereas the latter seems like a mere accident.

The simple regularity view ultimately fails as an account of laws because it is unable to distinguish accidentally true generalizations from lawful ones. There must be more to being a scientific law than simply being a true generalization, but what more is needed?

Sophisticated Regularity View

According to a more sophisticated version of the simple regularity view, laws are true generalizations, but not just any true generalizations count as laws. Rather, laws are those true generalizations that make up a particularly efficient systematic description of the entire universe. Let’s explore this idea in a little more detail.

Anyone can begin to describe the universe by just listing things that she knows: Grass is green, the Eiffel Tower is in Paris, electrons are negatively charged, and so on. If we knew absolutely everything there is to know about the entire universe, past, present, and future, we could continue

this list until we had described the universe in its entirety.

There are more and less efficient ways of describing the universe. Including “grass is green” in our descriptive list is more efficient than specifying each blade of grass by some coordinate system and saying of it that it is green, but is perhaps less efficient than saying that all chlorophyll-containing plants are green. The most efficient description of the universe is the one that is the *strongest*, by which we mean that it is highly informative because it logically implies the most information about matters of fact (such as that grass is green, electrons are negatively charged, etc.) in the *simplest* manner possible; that is, by including as few basic, nonderived, statements possible.

Strength and *simplicity* are what we might call *virtues* of a description of the universe because a description is better the more informative it is and the simpler it is. But these virtues *compete*. The stronger an overall description of the universe is, the less simple that description will be because it will contain a greater number of basic statements. And the simpler a description is—in other words, the fewer basic statements it contains—the weaker it will be because it will have fewer resources to directly say, or logically entail, true things about the universe.

The best description of the universe will be the one that strikes the optimal balance between strength and simplicity. According to the *sophisticated regularity view*, laws of nature are those true generalizations that either are, or are logically entailed by, the basic statements in the *best* description of the universe; that is, the one that strikes the optimal balance between strength and simplicity. There is no pressure on the best description to entail *all* truths about the universe, because a great many truths are of little to no interest to scientists—for example, my living room walls are green, postal boxes in the United Kingdom are red—and we wouldn’t want to count these as laws anyway. Truths about the universe that are not entailed by the best description will not count as laws of nature.

The idea, then, is that while *all gold spheres are less than 1 mile in diameter* may be true, it won’t be included as, or entailed by, any basic statements of the best description of the universe; that is, the one that strikes the optimal trade-off between

strength and simplicity. The generalization *all uranium spheres are less than 1 mile in diameter*, by contrast, will be entailed by some basic statement, perhaps about quantum mechanics, of the best description of the universe.

Thus, the sophisticated regularity view counts as laws just those regularities that are described, or entailed, by basic statements of a particularly efficient description of the universe. As well as the ability to overcome the gold spheres problem, the sophisticated regularity view enjoys a high degree of continuity with actual scientific practice. Scientists are interested in discovering and articulating the most general and informative facts about the universe and in explaining as much as they can about the universe with as few resources as possible. The sophisticated regularity view takes this observation about scientific practice—that scientists seek strong simple explanations—and makes it constitutive of what it is to be a law of nature.

Whereas continuity with science is generally seen as counting in favor of a philosophical theory of laws, some have expressed concern that the sophisticated regularity view's dependence on balancing *strength* and *simplicity* renders laws *mind-dependent*.

What counts as the best balance between the strength and simplicity of a description would seem to depend on contingent psychological facts about human beings. So, if human psychology were sufficiently different, then the system that struck the optimal strength–simplicity balance would be different, hence the *laws* would be different. However, the laws should not be contingent on human psychology, so the objection goes, so the sophisticated regularity view does not provide an appropriate philosophical account of the laws of nature. The defender of the sophisticated regularity view who does not wish to admit that laws are mind-dependent is thus tasked with developing wholly objective standards for evaluating the strength and simplicity of a description of the universe, but this is no mean feat.

Let us now briefly turn our attention to two further, but closely related, problems for the sophisticated regularity view, which have motivated the development of subsequent views to be discussed.

First, the sophisticated regularity view seems to get the order of explanation between laws of nature and facts about the universe the wrong

way around. According to some philosophers, it is intuitively obvious that scientific laws explain facts about the universe: a dropped vase falls to the floor *because* of the law of universal gravitation; a light ray entering a prism exits the prism at angle θ *because* of Snell's law; and so forth. However, according to the sophisticated regularity view, laws of nature merely *describe* facts such as those concerning falling vases and refracted light rays, and so it looks as if facts about the world explain the laws of science rather than the other way around.

A second, related, problem stems from the fact that had the world been very different from how it actually is, the laws of nature, according to the sophisticated regularity view, would have been different too. Since it is *possible* that the world was very different, laws turn out to be highly *contingent* because the matters of fact that they describe are contingent. But perhaps we think that scientific laws are *necessary*; that no matter how the world was, the laws would be just as they are.

Nomic Necessitation

Both regularity views are what philosophers would call “metaphysically lightweight”—they don't posit the existence of any unusual entities that are unfamiliar to common sense or modern science. This is not to say that they do not clash with common sense or science in other ways; we saw earlier that the simple regularity view bestows law status upon regularities that scientists would not deem laws. And both views arguably fail to capture the necessity and explanatory power of laws, features that some will say are why laws are so important to science in the first place. Furthermore, some philosophers have argued that quantum mechanical phenomena pose problems for the most influential versions of the sophisticated regularity view. The *nomic necessitation* view, to be discussed in this section, is less metaphysically lightweight, but its proponents think that this is justified by its other virtues.

The nomic necessitation view can be understood as agreeing with both regularity views that laws are regularities of the form “All Fs are Gs”; the disagreement lies in what *makes* a regularity a law. As before, the proponent of the nomic necessitation view will want to deem the regularities in

List 1 (plus “all gold spheres are less than 1 mile in diameter”) *nonlaws* and those in List 2 *laws*. To do this, they appeal to the idea that there exist such things as *universals* and *relations between universals*.

What are universals? One could think of universals as those entities in the world to which our predicates refer. So, just as names, such as “Aristotle” and “Napoleon” refer to the individuals Aristotle and Napoleon, *predicates* such as “... is red,” “... is human,” “... is massive,” refer to the universals *redness*, *humanity*, *mass*, and so on. It is often said that individuals *instantiate* universals, where instantiation is a special relation that holds between individuals and universals. Take the example of a red postal box: the individual, the postal box, instantiates the universal, *redness*. Indeed, many different individuals can wholly instantiate the same universal; unlike individuals, universals are multiply located and thereby account for respects of similarity between distinct individuals. Aristotle and Napoleon both instantiate *humanity*; postal boxes and cherries instantiate *redness*; electrons, bowling balls, and black holes instantiate *mass*. In each of these cases, instantiating the same universal accounts for similarity between distinct individuals.

The nomic necessitation view also requires *relations* between universals. More precisely, the view requires *necessitation relations* between universals. To get a sense of what we mean by “necessitation relations between universals,” consider the universals *redness* and *color*. One might think that a necessitation relation holds between these universals because, *necessarily*, anything that instantiates *redness* instantiates *color* too.

According to the nomic necessitation view, a regularity of the form “all Fs are Gs” is a law, if, and only if, there exist the universals *F-ness* and *G-ness* and a special kind of necessitation relation called a *nomic necessitation* relation, which we denote “N,” between *F-ness* and *G-ness*, which ensures that anything that is F is G too.

Nomic necessitation relations, unlike the necessitation relation between *redness* and *color*, hold only contingently. So, if it is a law that all Fs are Gs because N holds between *F-ness* and *G-ness*, it is nonetheless possible that N failed to hold and hence that it was not a law that all Fs are Gs. According to the nomic necessitation view, the

necessity with which laws are associated is weaker than the necessary connection between *redness* and *color*. This is thought by its proponents to be a benefit of the present view because, they think, although the laws of nature are necessary *in a sense*, they are not *absolutely* necessary because we can *conceive of* a world in which the actual laws do not hold (by contrast, we cannot conceive of a world in which something is red and not colored) and conceivability is thought (by some) to entail possibility.

The nomic necessitation view deems “all uranium spheres are less than 1 mile in diameter” a law because, it says, there exists an N-relation that holds between the universals *being a uranium sphere* and *being less than 1 mile in diameter*; “all gold spheres are less than 1 mile in diameter” is not a law because there is no N-relation that holds between the universals *being a gold sphere* and *being less than 1 mile in diameter*.

Since the obtaining or not of an N-relation between two universals is a completely mind-independent matter, the nomic necessitation view, unlike the sophisticated regularity view, is not subject to the objection that the laws are mind-dependent. Furthermore, laws, on this view are said to explain matters of fact, rather than the other way around; it is *because* it is a law that all Fs are Gs. In other words, it is because an N-relation holds between *F-ness* and *G-ness*, that any particular F is also a G; N-relations play a *constraining*, or *governing* role, which explains certain matters of fact.

Finally, laws, on this view, are said to enjoy the appropriate *necessity*; if N holds between *F-ness* and *G-ness*, then it is *necessary* that anything that is F is G too.

The nomic necessitation view is not without its problems. Perhaps the most straightforward source of concern is the fact that the view is not metaphysically lightweight. All of the work is done by *necessitation relations between universals*. But we are well within our rights to be skeptical about the existence of universals, let alone necessitation relations between universals. What, exactly, *are* these things and *are* we really justified in believing in them? Universals and necessitation relations don’t seem like other entities familiar to science. It’s not as if we can discover universals and necessitation relations with a sufficiently

powerful particle accelerator. Rather, they are entities posited by philosophers from the comfort of the armchair. But why think that the philosopher's armchair methods can license belief in such peculiar entities?

Relatedly, we may wonder how necessitation relations are supposed to do the work for which they are invoked by the philosopher. A necessitation relation, *N*'s, holding between the universals *F-ness* and *G-ness* is supposed to make it necessary that all *F*s are *G*s. But why is this so? Why couldn't *N* hold between *F-ness* and *G-ness* and yet there still be an *F* that is not a *G*? As David Lewis, a staunch advocate of the sophisticated regularity view, memorably put the point in opposition to David Armstrong, a pioneer of the nomic necessitation view:

I say that *N* deserves the name of 'necessitation' only if, somehow, it really can enter into the requisite necessary connections. It can't enter into them just by bearing a name, any more than one can have mighty biceps just by being called 'Armstrong.' (1983, p. 366)

Advocates of the sophisticated regularity view and the nomic necessitation view do, however, agree, in one important respect, about the nature of physical properties. Physical properties such as charge, mass, and spin are important when it comes to scientific law because laws of nature seem to articulate regularities that are about these properties. Coulomb's law, for example, says that two distinct instances of charge will exert a force on each other proportional to the magnitude of each charge and inversely proportional to the square of the distance by which they are separated. The sophisticated regularity view maintains that laws, such as Coulomb's law, describe how properties are distributed throughout the universe, and the nomic necessitation view maintains that laws are necessitation relations between universals that determine the distribution of properties throughout the universe—this, in essence, is the disagreement between these views. Where the two agree, however, is in the idea that properties could, in the very broadest sense of *could*, be distributed in any way imaginable. They both agree that there is nothing about the property charge, for example, that determines how instances of charge are

distributed and so nothing about charge that determines that instances of charge behave in accordance with Coulomb's law (similar comments apply to other property-law pairs).

This view of physical properties has been held up by some philosophers as a further source of concern for both the sophisticated regularity view *and* the nomic necessitation view. If physical properties are so *thin* as to impose no constraints on the laws that they enter into, it is hard to get a grip on what physical properties really *are*.

The contingency of the connection between properties and laws opens up the possibility that the property that we call *mass* is featured in Coulomb's law and the property that we call *charge* is featured in Newton's law of universal gravitation. In other words, it is possible that mass and charge swapped theoretical roles, which strikes many as very odd indeed. But worse still, since properties and the lawful behaviors with which they are associated are thoroughly contingent, there is no way of *knowing* which property or properties are playing which roles in our scientific theorizing about the laws—properties and their true natures are rendered irrevocably beyond our ken.

Dispositional Essentialism

Dispositional essentialism takes as its starting point dissatisfaction with the thin view of physical properties shared by the sophisticated regularity view and the nomic necessitation view. Rather than conceiving of natural properties as thin and inert, dispositional essentialism maintains that properties have rich *essences*, which determine the laws that they enter into. So, in the same way that you or I may be said to be *essentially* human (but perhaps only accidentally philosophers) properties are *essentially* certain ways too. *Laws*, then, are not imposed on properties, either as external descriptions or necessitation relations; rather, they emanate from the essences of properties themselves because they concern property essences.

According to dispositional essentialism, a regularity such as "all *F*s are *G*s" is a law if, and only if, it holds in virtue of the *essence* of some property or properties. If it is part of the very nature of the properties *F* and *G* that *all F*s are *G*s, then it is

a law that all Fs are Gs. If, on the other hand, all Fs are in fact Gs but this has nothing to do with the essence of any property, then the regularity is merely accidental and not a law.

Returning to our example, dispositional essentialism maintains that it is part of the *essence of charge* that charged individuals interact in accordance with Coulomb's law; in other words, that distinct charged individuals exert a force on each other proportional to the magnitude of the charges and inversely proportional to the square of the distance of separation. Since this is part of the essence of charge, it is not possible that charged individuals failed to interact in accordance with Coulomb's law. So, the odd result (yielded by the thin view of properties shared by the sophisticated regularity view and the nomic necessitation view) that charge and mass, for example, could swap roles and hence that we cannot ever know the true nature of physical properties, is avoided.

Dispositional essentialism yields a simple response to the gold spheres problem, too. It is of *the essence* of some property or properties that there are no uranium spheres greater than a mile in diameter, so it is a law that there are no uranium spheres greater than a mile in diameter. By contrast, there is no property or properties the essence of which makes it the case that there are no *gold* spheres greater than a mile in diameter, so it is merely an accident that there are no gold spheres greater than one mile in diameter.

There is no mind-dependence problem for dispositional essentialism; it is a completely mind-independent matter whether or not it is of the essence of some property that a given regularity holds, so scientific laws are completely mind-independent phenomena.

The question about *order of explanation*, "Do laws explain matters of fact or do matters of fact explain the laws?" is arguably a vexed one for dispositional essentialism. If one interprets laws as describing the essences of properties, it looks as if matters of fact concerning properties and their essences explain the laws. If, however, one interprets laws as *constituents* of property essences—for example, Coulomb's law is part of the essence of *charge*—then one could maintain that laws, so understood, constrain how properties are distributed throughout the universe and, thereby, explain matters of fact. This way of viewing things is not

so far from the nomic necessitation view—on the latter view, laws are necessitation relations between universals that constrain property distributions; on the former, laws are constituents of property essences that constrain property distributions. On both ways of looking at things, then, laws are metaphysical *constraining* entities that determine property distributions and hence determine and explain matters of fact. The obvious difficulty, then, for dispositional essentialism, and shared with the nomic necessitation view, is that of responding to the demand to say more about how, exactly, the laws are supposed to do this constraining work.

Assuming that dispositional essentialism's laws are up to their task, these laws turn out to be necessary in quite a strong sense. Laws concern the essences of properties, so, it is not possible in any sense for properties and the laws with which they are associated to come apart (*compare*: It is part of your essence that you are human, so it is not possible for you to exist and not be human). Instances of charge must behave in accordance with Coulomb's law, for example, because Coulomb's law holds in virtue of the essence of *charge*. The nomic necessitation view, by contrast, allows that instances of charge may not behave in accordance with Coulomb's law if the relevant necessitation relation is not present.

Philosophers disagree on whether the necessity of the laws yielded by dispositional essentialism is an advantage or a disadvantage. Those who think that it is a disadvantage typically believe that conceivability, or what we can *imagine*, is our best guide to what's possible. They argue that since we can imagine instances of *charge* behaving in a way that violates Coulomb's law, it is not necessary that *charge* is governed by Coulomb's law. Others think that conceivability has nothing to do with what's possible and that the laws' being strongly necessary best explains why laws of nature are so important and useful, features that are hard to make sense of on the assumption that the laws are contingent. Some philosophers have even argued that the necessity of the laws yielded by dispositional essentialism does not go far enough because it still allows for the possibility of *alien* properties and laws—merely possible properties that are not actually instantiated anywhere or at any time and which are governed by

completely unfamiliar laws—and this, they argue, severely compromises the laws' necessity and any potential benefit therein.

New Directions

The philosophy of laws is a burgeoning field, and within the spatial constraints of an encyclopedia entry, it's possible to trace only a limited number of lines through this fascinating area of research. Let us now examine some new research directions before taking a final look at the broad philosophical issues raised in this entry.

Structuralism

The philosophy of scientific laws is entwined with the philosophy of *modality*, that is the philosophy of possibility and necessity. This was seen in the preceding discussion of whether and to what extent the laws are necessary. In general, we may think that laws play a role in determining the limits of what is possible. *Ontic structural realists*, motivated by developments in current physics, argue that the world fundamentally *is* a modal structure. That is to say, there are no individual objects at the fundamental level of the world, just modal structure. And when pressed on what they mean by this, they typically cite laws of nature. So, according to ontic structural realism, such laws are the modal building blocks of our world.

Combination Views

Some philosophers have defended a combination of the sophisticated regularity view and dispositional essentialism. These views combine a broadly dispositional essentialist account of properties, according to which properties have rich essential natures that constrain how they are distributed, with the idea that scientific laws are features of an efficient *description* of property distributions throughout space and time. This combination, they argue, is able to avoid certain problems for regularity views and dispositional essentialism while also reaping benefits from both sides such as continuity with science (from the regularity view component) and the necessity and explanatory power of laws (from the dispositional essentialist component).

Pragmatism

There is a recent trend among some proponents of the sophisticated regularity view to, in a sense, embrace the partial mind-dependence of laws. These philosophers argue that laws ought to be useful tools for creatures *like us*; that part of what it is to be a law of nature is to be something that enables us to make predictions and facilitates the manipulation of our environment to our own ends. Since what counts as useful for us will, to an extent, depend on our *minds*, the laws are partially mind-dependent. But these philosophers think that this is as it should be if we are to provide a sensible philosophical analysis of laws that is genuinely continuous with actual science.

Conclusion

As this entry has shown, there are various issues of broad philosophical interest around which the question "What is a scientific law?" turns. These include the following. *Coherence with intuitions*: To what extent do we wish to accommodate, for example, the intuition that it is a law that all uranium spheres (but not gold spheres) are less than one mile in diameter? *Continuity with science*: To what extent do we want our account of laws to cohere with the scientific conception of laws? *Mind-(in)dependence*: Can we tolerate a degree of mind-dependence of laws if this achieves continuity with science and perhaps other benefits, or must laws be completely mind-independent? *Metaphysical posits*: Are we willing to accept the existence of universals, necessitation relations, property essences, and governing forces if these yield certain benefits such as explanatory power and the necessity of laws? *Modality*: In what sense are the laws necessary and where does this necessity come from?

LAWS OF NATURE

Historically, laws of nature have played a role in the explanations or descriptions of order in the universe. As such, understanding laws of nature is an important task in philosophy of science and the sciences. Understanding laws has traditionally pursued two incompatible paths. One path is nomological realism, where laws have their own metaphysical existence and underlie the patterns and regularities of nature. The other path is typically called the *regularity tradition*, where laws are taken to be descriptions of the regularities and patterns that we find existing in nature. There are only regular patterns, but no presumed metaphysical basis, underlying these regularities. Alternative paths seek to understand laws in terms of causes or dispositions, counterfactuals, and constraints. Philosophers usually think of scientific laws—the laws scientists state in their models and theories—as approximations to the laws of nature.

Nomological Realism

Nomological realist accounts posit a metaphysical existence for the laws of nature. Laws are fundamental to reality and are often thought of as *governing* the behavior of the events and patterns we experience in the world because there is a form of necessity at work in the law itself. The laws of nature are conceived as having a kind of metaphysical autonomy, and everything that happens in the universe follows because of the laws. This is a prescriptivist view of laws of nature.

Universals Accounts

Universals accounts posit that laws are grounded in necessary relations among universals. A universal is a class of mind-independent entities such as red or round. Universals are qualities or properties that individuals can share. For instance, a particular ball can be red and round, as can a particular ornament. Universals accounts formulate law statements as “All Fs are Gs,” where the universals F and G cannot be further reduced to anything more basic.

An example under this account would be “All electrons have charge $-e$,” where e represents the

exact magnitude of the charge. Electrons are basic particles that cannot be reduced to any constituent parts and share the universal electron-ness; the magnitude of the charge e cannot be further divided. The law statement is taken to be true because both electron-ness and e are universals where the relation between them is one of necessitation. The law is thought to explain why we always and only see electrons with the same magnitude of charge.

The nature of the necessitation has two possible elaborations. One branch will say that the necessitating relationship between electrons and charge is one of necessary governance: Electrons have the charge $-e$ by virtue of the law of nature. The form of necessity may be further specified as being physical or metaphysical necessitation. The other branch will say that the charge $-e$ necessarily inheres in the electron as a physical or metaphysical necessity. On either branch, laws of nature are prescriptivist.

Proponents argue that nomological realist accounts make sense of counterfactual reasoning that is a staple in scientific investigation. For instance, if we know that “All electrons have charge $-e$ ” is a necessity, scientists can reason through questions such as “If a magnetic field of X configuration were applied to electrons, how would their motion be affected?”

Laws as Primitive

This kind of nomological realist account assumes that laws of nature are primitive or fundamental necessities. Every theory, metaphysical system, or ontology must have something that is unanalyzable and basic. An example would be Euclidean geometry with its five fundamental axioms as unanalyzable primitives. The laws, then, are the basis for explanation for all patterns such as “All electrons have charge $-e$.” As such, it is left unanalyzed whether electron-ness and charge are universals and whether the necessary relationship between them is one of governance or inherence.

Regularity Accounts

Proponents of nomological realist accounts believe there must be some underlying *metaphysical glue* holding the world together. In contrast, regularity

accounts assume there is no physical or metaphysical necessity at rock bottom making the patterns and regularities of the world what they are. Rather, the patterns simply are what they are. Laws of nature, then, are descriptivist—they describe the patterns we find in nature.

It is rare to find anyone defending a view of regularities as simple as this. For one thing, it is not able to distinguish between accidental truths such as “All gold spheres are less than a mile in diameter” from the kinds of regularities that are crucial to scientific explanation like “All electrons have charge $-e$.” Another difficulty is that this simple regularity view runs into problems grounding inductive inferences. Instead, defenders of regularity accounts have developed more sophisticated approaches.

As a historical note, it is common in the philosophy literature on laws of nature to speak of regularity accounts as “Humean,” referring to the Scottish philosopher David Hume (1711–1776). Although Hume believed we come to associate patterns such as cause and effect through our experience of observing events occurring together (e.g., that rocks fall when dropped), he was a firm believer in laws as representing necessities. What Hume questioned was our empirical access to, our ability to know, these necessities. Hence, it is not historically accurate to refer to regularity accounts as Humean accounts.

Best-Systems Accounts

To handle issues with scientific inferences, best-system accounts seek to organize the truths representing regularities into an ordered system that supports deductive inferences modeled on Euclidean geometry. The idea is that laws of nature are those descriptions of generalizations that would appear at the base as axioms in the system. The axioms are chosen to fit the best combination of content, strength, and simplicity. If well designed, the system supports derivation of observations from the laws plus a specification of the context. This is the spirit of how Isaac Newton’s laws of motion applied to particular contexts allow for derivation of motion such as the behavior of a swinging pendulum.

When scientists discover that a regularity they thought was a law actually is not (perhaps because they were mistaken about the regularity or

discover it is a consequence of a more basic regularity), it is possible to adjust the system by replacing the regularity in question with a more appropriate one. Therefore, the existence of a best system does not preclude revising our knowledge on the basis of empirical findings or discovering new laws.

Best-system accounts make sense of scientists' counterfactual reasoning in terms of the structure of the best system by using the knowledge of the patterns functioning as axioms: Scientists derive how a change of magnetic field configuration *X* will affect the behavior of electrons using the laws describing persistent patterns.

Causal/Dispositional Accounts

Some accounts of laws of nature attempt to avoid the metaphysical glue of nomological realism as well as the mere descriptivist nature of regularity accounts. One of these alternatives is to ground the persistent patterns of nature in causal capacities or dispositions. It is these capacities or dispositions that are the truth-makers for laws of nature.

An example would be that electric charge necessarily has the disposition to repel like charges. This disposition underlies the law that particles with like charges repel each other (e.g., two electrons), while particles with opposite charges attract (e.g., electron and proton). Hence, causal or dispositional accounts end up locating some form of necessity in the capacities or dispositions in nature rather than in the laws. There is still a form of metaphysical glue that explains the laws of nature.

Counterfactual reasoning on these accounts would look at how a change in a causal capacity would lead to an observable change. For instance, if a change in a magnetic field is made to configuration *X*, this will change its disposition to affect electron behavior.

Counterfactual Accounts

The need to support counterfactual reasoning about laws of nature and concrete situations appears in all accounts of laws. Hence, another alternative to either nomological realist or regularity accounts is to move directly to laws as

counterfactuals or as underwritten by counterfactuals. Roughly, the idea is that instead of thinking laws of nature support counterfactuals, it is counterfactuals that support laws of nature.

To make sense of counterfactual accounts, we need the concept of possible worlds. Possible worlds are defined as a set of propositions that are true of the entire history of a universe or as the entire set of facts that compose the history of a universe. For example, the total set of facts comprising the history of our universe is the actual world, so it is a possible world. So, too, is a universe where all the facts are the same as the actual one except that you are half an inch taller. So, too, is a universe where all the facts are the same up to Japan's surrender in World War II before any atomic bombs were dropped. In a sense that can be made more precise, the possible world where you are a half inch taller is closer to the actual world than the possible world where Japan surrenders early.

Counterfactual accounts of laws focus on sets of possible worlds that share the same laws of nature as the actual world and then explore variations. Counterfactuals themselves are spelled out in terms of the differences in the possible worlds (e.g., in terms of differences in the propositions comprising the entire history of the different possible universes). What it means to be a law of nature is spelled out in terms of the kind of necessity that can be defined for a set of possible worlds. This necessity, in turn, is grounded in the counterfactual propositions true in these possible worlds. The relevant kind of necessity is not metaphysical or physical necessity, but a modal necessity depending on grades of possibility.

Constraint Accounts

The foregoing analyses focus almost exclusively on the status of law statements such as "All electrons have charge $-e$." However, in actual scientific practice, laws typically refer to equations (usually in the form of differential equations) expressing relations among variables and forces describing the evolution of a system state. Such equations and states show up in models of physical systems. An example would be Newton's second law, $F = ma$, where F represents a mathematical model for the force acting on a particle, a is the

acceleration or rate of change of the particle's velocity, and m is the particle's mass.

Constraint accounts capture these aspects of scientific practice while steering a course between nomological realist or descriptivist understandings of laws of nature is. The modeling of forces and system states in physics generally is carried out in terms of energy and constraints. Such models are defined over a state space, an abstract mathematical space of points where each point represents a possible state of the system. This defines the space of possibilities for the system. An instantaneous state of the system is characterized by the instantaneous values of the variables considered crucial for a complete description.

Laws of nature, on this account, constrain the action of forces along with other constraints of system behaviors. The constraints can be physical, dimensional (e.g., some forces behave very differently in two dimensions vs. three), dynamical (e.g., due to the dynamics of system behavior that arises over time), and so forth. Physicists pay attention to the constraints defining the particulars of a physical context to understand system behaviors. In fluid convection, for instance, the emergent large-scale fluid rotation constrains possible motions of smaller scale fluid molecules under the action of gravity (which itself is constrained by spatial dimension).

The most fundamental laws are those that define the total space of physical possibilities for the universe as a system and its subsystems. Yet, these laws do not dictate the behavior of any systems but constrain those behaviors to be physically possible. Further constraints restrict both the kinds of systems that can exist and their behaviors. Hence, chemical or biological laws and properties constrain system behaviors further to specific regions of possibility space, yet never violate the fundamental laws—never lead to behavior that violates the fundamental constraints of physical possibility.

On constraint accounts, laws of nature are constraints, so are not mere descriptions. On the other hand, no appeals to metaphysics are needed to explain why systems such as the solar system behave as they do. Constraints, forces, and energy in their contingent configurations are primarily responsible for the behavior of systems studied by physicists constrained by fundamental laws plus any laws that emerge over time. Additional

constraints and properties are needed for explanations of geological or biological systems.

Statistical Laws

Statistical laws are very common in the sciences. For example, radioactive decay is a statistical phenomenon. Consider a sample of Uranium 232. In 1 hour, we can say on average how many nuclei will undergo a decay event but cannot say specifically which nuclei in the sample will decay. What we observe (and what physicists derive from physical principles) is that these decay events will conform to a statistical regularity, a statistical law. Scientifically, the randomness of such systems always exhibits a form of order. Order that is different from deterministic order, to be sure; nevertheless, randomness observed by scientists always is statistically ordered.

How do different accounts of laws of nature make sense of statistical laws? Nomological realists struggle with how to make sense of an appropriate form of necessity that yields statistical behavior. One way out of this struggle is to assume that all statistical behavior has an underlying deterministic basis so that all statistical behavior is epistemic only—a lack of knowledge about or empirical access to this underlying basis. Primitivists can simply posit brute statistical laws as basic to the universe.

Proponents of causal/dispositional accounts also struggle with statistical laws. Some accounts try to invoke statistical behavior as a reflection of our lack of epistemic access to an underlying deterministic disposition. Others explore statistical or indeterministic forms of causation as possible explainers for statistical laws.

Similarly, proponents of counterfactual accounts choose between counterfactuals that represent ignorance of an underlying deterministic basis, or between exploring statistical counterfactuals.

On regularity accounts, statistical laws are simply descriptions of statistical patterns observed in nature. Such accounts can remain neutral about whether observed statistical behavior is epistemic or represents randomness that is irreducible to a deterministic basis.

For constraint accounts, statistical behavior depends on the relevant laws constraining system behavior, as well as contingent conditions providing additional constraints that locate concrete

system behavior in either deterministic or indeterministic portions of physical possibility space. The laws as part of the total context play a role in whether behavior is statistical or not.

LIFE SCIENCES, CONTEMPORARY

Theories and the life sciences enjoy a special relationship. For some, theories about the natural world—explanations of nature at the level of fundamental laws and rigid causality—are still the main goal to achieve, the sign of biology maturing into an exact science in the 21st century. For others, the life sciences are on the brink of a sea change in scientific explanation. Understanding the complexity of organismal life and organization consists not in reducing its complexity to constitutive elements and their causal relation but in the reverse process of simulating the behavior of the entire system and then inferring from the dynamics of the procedure how the system works.

Although space does not permit this entry to offer a comprehensive account of the life sciences or the concept of theory itself, it does aim to

elucidate the place of theory in the contemporary life sciences. In the words of the Italian philosopher, physiologist, and priest Lazzaro Spallanzani, it sheds light on some relevant constellations just as a “mirror . . . changes the appearance of objects” (1803, p. 326).

Nature, Science, and Scientists

The usefulness of theories hinges on the ability to validate them: Theories provide predictions that can be tested. They are analytical tools which subject themselves to examination for logical correctness and consistency; they formulate a set of mechanistic explanations of known facts which lead observed patterns and regularities back to underlying principles; they form a unifying framework which can reconcile and explain a multitude of empirical findings, even contradictory ones; they give biological findings, framed in terms of mathematical formalizations, logical rigor, unambiguousness, and stringency.

In nature, the life sciences have a research topic which is resistant to these forms of examination as practiced in the contemporary scientific theory and philosophy of the exact sciences, above all physics. There is, on the one hand, the subject itself: Nature is diverse and complex. It is the epitome of abundance: a profusion of variety and form, an incalculable diversity of existing organisms, and open to the future. Nature is also both topical and historical as well as coincidental. As such, it bears the past of its evolution within itself, a past which continues the living into a series of possible futures without determining the future or making it predictable. Nature is, after all, *becoming*, not *being*. Living is principally a continuous process, constantly active and permanently in transition. Susceptible to the fleeting details of everyday changes, living beings are part of an environment which they create and which has created them.

That leads, on the other hand, to a host of independent sciences devoted to this nature: botany, zoology, ecology, genetics, evolutionary biology, physiology, cell biology, epidemiology, and paleontology are just a few disciplines united under the umbrella concept of the life sciences. Each constitutes an individual field of know-how, with a distinct body of knowledge, questions, methods, and practices.

Third, and no less important, is the role of the scientist whose expertise is incumbent on the testing of theories and models. In the 21st century, the fragmentation of knowledge and the increasing specialization of scientific research cast a spotlight on the institutional, communicative, and participatory organization of science in addition to the purely technical and substantial competence of individual scientists. The scrutiny of a mathematical model or theory about a biological matter is essentially a question aimed equally at the competence of the biologist, who is expected to understand the mathematical formulation of biological matters, as well as at the mathematician, who must be informed about the biology of what they formulate in mathematical terms. For decades now, ever new courses of study, curricula, and interdisciplinary centers have been established at universities and research facilities around the globe whose aim is to merge the biologist and mathematician into the competences of a single person. In fact, what is being demanded here is a much wider spectrum of specialist knowledge, since the interdisciplinary research structure of the contemporary life sciences often brings all manner of biologists, computer scientists, mathematicians, physicists, and chemists together in one laboratory just as, for example, marine biologists, microbiologists, and ecologists set out together on an Arctic expedition. Declaring the validity of theoretical knowledge is, alongside the need to be commensurate with epistemology and exert due to logical care, thus also a process of the disciplinary negotiation of meaning; achieving consensus on the use of words, formulas, and images in which knowledge is captured; as well as the attribution of authority to the infrastructures, institutions, and spokespersons that produce this knowledge.

History, Philosophy, and Theory

The philosophy and history of science—and particularly *Erkenntnistheorie* or epistemology, the theory of knowledge—have long pondered the relationships and dynamics, analytical as well as historical, of the many ways of thinking and reasoning in the life sciences from their beginnings to the present day.

From a historical perspective, theories become the subject of narratives. Whereas in the past these

were often narratives of progress—in the sense of the increasingly successful theoretical grasping of a subject often associated with hierarchies of value—historical epistemology adopts an approach that treats the sciences themselves as a historical object. As the philosopher Gaston Bachelard noted, the social, cultural, and technical conditions of science in a particular place at a particular time are historically called into question here as the conditions of possibility for the coming and going, transformation and legitimization of research objects, epistemic categories, the science(s) and knowledge *tout court*.

Arguably the most famous theory in the history of biology, Charles Darwin's theory of evolution is an example of a theoretical edifice in various guises. In the 19th century, Darwin's theory of evolution by natural selection presented a mechanism to explain how populations of organisms change over time. Darwin himself called *natural selection* a theory even if he regretted having too little understanding of mathematics to be able to give mathematical form to his idea. This was first achieved by population genetics. Independently of one another, the German doctor Wilhelm Weinberg and the British mathematician Godfrey Harold Hardy formulated the Hardy–Weinberg principle in the early 20th century. Natural selection, according to this basic premise, only occurs where sufficient genetic variation exists in a population. Given an ideal population, the Hardy–Weinberg principle states that genetic variations remain constant under certain circumstances, namely in the absence of selection, mutation, migration, or genetic drift. Although in reality there are no ideal populations, the algebraic formula is nevertheless suitable for making predictions about the relative frequency with which a gene (dominant or recessive) is to be found in an actual population. The British statistician and geneticist Sir Ronald Fisher employed mathematical and statistical methods in his 1930 publication *The Genetical Theory of Natural Selection* and thus provided numerous concepts and models, such as Fisher's fundamental theorem of natural selection, Fisher's principle, and Fisherian runaway selection.

Whereas population genetics concentrates on the genetic occurrences in a population, the mathematical game theory models their evolution in the framework of competing strategies within a

population. The cooperative and competitive behavior of individual protagonists is modeled in a game-theory framework of contests, strategies, and frequencies with which they are applied. In this context, games are the name for mathematical objects which function according to different rules since they formalize varying forms of behavior, strategies, and problems within a population. Another way of formulating natural selection in mathematical terms is via the incidence of mutations; that is, via the dynamics of the population's evolutionary change, as evolutionary invasion analysis, for example, has been doing with the tools of dynamical systems theory since the end of the 20th century.

By contrast, philosophy and the theory of science analyze the various ways of targeting theoretical knowledge about nature in terms of logical rigor and robustness, and the degree of formalization they achieve. Alternatively, they fundamentally question the concept of theory for the biological world. Epistemologically, the arguments revolve around the unique characteristics of life. What is called into question is whether theories, if it is possible to formulate them, can capture the living world with physical, mathematical, and chemical descriptions or just the elements they share with them, but not those which go beyond.

Within the epistemic diversity of theoretical concepts in the life sciences, hypotheses and models occupy a special place. As a rule, the hypothesis precedes the theory: the one taken as the mere suggestion of an explanation, the other as a technical and robust working out of a hypothesis into a theory. Experimentation, on the other hand, the controlled empirical setup for the acquisition of data, is alternatively considered as guided by hypotheses or informed guesswork—rarely taking place in the framework of a fully fledged theory but just as a mere tool for data collection—or itself considered a model system of its own Rheinberger (1997). The term *model* is the most dazzling of all and, according to some observers, currently over-used as Morgan & Morrison (1999). The notion of a model encompasses concepts, materials, practices, computation, or images and also extends to robotics and artificial intelligence. It figures as an intermediary, a bridge between theories and data. Rather than devaluing the term, the

abundance of modeling strategies is valued as the characteristic combinatory style of reasoning in the field following on from the complexity of the biological world.

Data, Dynamics, and Computers

Recent developments in the life sciences add to the epistemic conundrum of the study of nature. Computation, engineering, and data acquisition have been key to advances in the 21st-century life sciences. Most notable is the rise of systems biology, which is the attempt to study life by regarding it in its complexity, examining it computationally, and providing types of explanation different from those previously known in the history of biology. Other developing fields such as synthetic biology continue to build organismal life from scratch. To this effect, they employ a growing and increasingly sophisticated number of technologies and foster epistemologies that equate the artificial *making* of biological worlds with the classic scientific forms of understanding and explanation, if not claiming it a superior one.

Faced with an unprecedented deluge of data, some have been prompted to imagine the end of theory altogether and others to embrace computation and engineering as approaches to rescue biology from observation and experiment, for centuries the pillars of knowledge acquisition about the natural world. Instead, they claim that computation and engineering will finally allow biology to enter a new era of hypothesis and theory-driven research. The computer, especially, is set to open a pathway to new kinds of theoretical knowledge via computational modeling and simulation.

With the large-scale investigation of the dynamics of biological systems and attempts to predict their behavior, the life sciences are finally breaking new ground. Along with this change in perspective comes a revolution in the visual imagery of the life sciences, where computer animations have become ubiquitous and central to working with, making sense of, and communicating, the otherwise impenetrable data.

In order to depict the changing landscape of the life sciences in the post-genomics era, a series of alternative epistemological frameworks has been put forward: Contemporary research is described, by Creager et al. (2007) for example, as “science

without law” as “data-centric” by Leonelli (2016), and by Fox-Keller (2003), as proceeding via “modelling from above” Wise (2004) by contrast calls it “growing explanations.” For scientists in the field, their work is frequently the more mundane practice of “tinkering” and “reasoning for results” as Bray (2001).

Historically rich in diverse practices, concepts, and competing approaches, the life sciences continue to develop manifold ways of thinking and reasoning about the living world that do not necessarily amount to theories in the aforementioned sense. Instead, there are many ways of pursuing theoretical knowledge in the life sciences, which may or may not contribute to a more unified understanding of the biological world at large. Theory in biology, in other words, is conducted in models, visualizations, simulations, and concepts; it is pursued with wet lab and *in silico* (computer-model) experiments; and it is not limited to mathematical formalization but also pays attention to the epistemological foundations of defining knowledge about the baffling wealth of the biological world.

Among the most notable novel tools in this shifting 21st-century scientific landscape are two which are performed on the computer but which have an impact far beyond the realms of science: trial theories or simulations, and computer animations; in other words, moving data.

Computer Simulations

Computer simulations emerged in the context of physics and the Second World War but have grown to become a ubiquitous tool in practically all fields of science over the last half-century. Having only come to the fore in the life sciences at the turn of the new millennium, they make it possible to study aspects of nature which were less accessible or completely inaccessible with the previous repertoire of techniques, tools, and practices. First, simulations target the complexity of the biological world; second, they investigate the living world as a dynamic system; third, they aim to predict the future behavior of large systems with the goal of intervening in and, if possible, controlling the developments to come.

Simulations are a tool of the moment, which reflects the interdisciplinary reality and dynamic

alliances of scientific and technological expertise in life science research. Their power is that “glue” and “compromise” Sismondo (1999) due to their ambivalent nature they create new cross connections to long-established scientific demarcations: They not only cut across disciplines but also across analysis and prediction, understanding and doing, and science and technology. They thus permit the integration of previously heterogeneous bodies of knowledge.

That hybridity of simulations compels science to traverse its narrow academic boundaries and become an actor in the world in hitherto unseen ways. Because they address real-world problems on a large scale, such as the evolution of entire ecosystems or climate change, and are designed to predict their development, thereby revealing ways to intervene in the course of processes, simulations are not only in themselves a scientific object in motion (technically working through constant algorithmic iteration), they also create shifting webs of activities spanning from scientists to activists.

In stark contrast to the reductionist tradition of taking things apart, which has characterized biology for centuries, a field such as systems biology integrates data from the microlevel of cells and proteins into organs and entire organisms to tackle biological complexity.

A whole range of simulation techniques are deployed in the life sciences. *Monte Carlo simulations*, based on random numbers and stochastics, can be used, for example, to model intracellular molecular transport; *agent-based modeling* focuses on the rule-based interaction of independent agents (individual or collective) and can be applied to investigate the behavior of—for example—animals in populations interacting with each other and the environment; *cellular automata* have a long history in biology and model the dynamics of systems and their various states dependent on their neighbors and are thus useful in studying biological pattern formation or the motion of fluids at the microscopic level; *neural networks* are part of the field of machine learning in which the instructions, given in the form of algorithms, are inspired by the neural network of the brain; and *finite-element simulations* are an engineering method to calculate the deformation of given structures by discretizing them and solving a set of differential equations. In

embryology, for example, they are employed to understand the development of morphological structures in ontogenesis by calculating shape changes in early gastrula formation.

Operating on the level of entire systems and their behavior, simulations enforce the study of the living world in its temporal unfolding. They frame organisms as beings in time, processing information in time and constantly integrating various levels of time including the temporal regimes of nanoseconds in cells and subcellular structures, diurnal rhythms, or life cycles and evolution.

The dynamics of life come to the fore in simulation techniques because the iterative structure of simulations mimics the processual character of nature. Put simply, computer simulations are mathematical models. In order to run them on a computer, some models are discretized versions of the mathematical laws assumed to rule the natural process in question. Other models implement no physically or chemically significant algorithms but reproduce the behavior of a system on a phenomenological or statistical basis. In the computer, a range of dynamic phenomena become analytically tractable that have previously been out of reach of mathematical formalization and its main tool, differential equations. Once implemented, those models are run on the computer, and one can follow how the iteration of the same set of rules again and again produces some kind of outcome or rather a range of outcomes. It therefore follows, as noted by Stephan Hartmann, that simulations work by way of one process imitating another.

Initially, simulations were employed to test hypotheses, guide the design of an experiment, explore and tune the range of parameters, or fit the experimental setup optimally to the material and intellectual resources available. Increasingly, however, they are used to predict the outcome of a process. Prediction is considered a prime element of theory; simulations, however, are applied in fields of biological inquiry where there is no theory. Simulations have therefore been lauded as trial theories and computation, previously a tool to apply theory, as the novel agent of building theories.

Scientific Animation

Imaging technologies are vital to the acquiring and processing of data, the analysis of simulation

results, and the display of dynamic biological features. Revolutionary advances such as live cell imaging allow us, for example, to trace the processes of meiosis and mitosis, see molecular motors transport organelles in the cytoplasm, or follow leukocytes on their way to the site of inflammation in their temporal dynamics, *in vivo*, in a live specimen.

Even if they are generated by technical means—including fluorescent genes, high-resolution laser microscopes, and magnetic resonance—the imagery of contemporary life sciences is, on the one hand, natural images in the sense of images of nature. As computer-generated and animated technical images, they create a sensory perception of processes in nature, and it is this visualization that opens up a new understanding of nature as we regard its movements and processes. On the other hand, these images are also an experiment, a mathematical model, and an algorithm. With the aid of technical tools, they produce a dynamic manifestation of nature to which the human sensory apparatus has no access. In addition, the numerous imaging technologies serve in the first place as a vehicle to digitize information. Data of subcellular processes, generated with the aid of a microscope, are no longer seen and analyzed by a human viewer but registered and further processed by a computer program. The images are therefore the visual result of numerous conversions between experiment and observation, organism and computation, and the material and the virtual realm. With the imaging of living organisms under life conditions, experimenting with the living body, building models, and imaging organic processes as they proceed in time are performed in unison. Previously, separate analytical categories thus collapse into a single domain of knowledge, with unknown consequences for the future conduct of research.

Extremely complex processes, such as embryogenesis, the development of a new organism from a single cell, are a field in which the approach of systems biology—studying the behavior of a system as a dynamic whole—constitutes both a major challenge and a radical turning point in research culture. The process of formation is a coordinated progression of spatiotemporal, synchronized cell movements which can be observed in the computer simulation as a direct motion sequence. *In vivo* imaging technologies like those

described above track every single cell from every angle, moment by moment. Systems approaches thus make it possible to generate massive sets of data. These are the prerequisite for the modeling of development in computers. If the data are sufficiently detailed, the research will lead to a computer model of embryogenesis that is able to make predictions about the behavior of the system and consequently intervene in the various parameters of this process at any time and place whatsoever.

The animated images of embryonic development are not just digital visualizations of a process. The embryos are no longer simply depicted in the trajectories of fluorescent cells on a dark screen. What we see is not merely development in four dimensions, a highly complex process of coordinating and differentiating a single cell into its thousands of successors. The embryos are now themselves a computer program, and their development can be studied and controlled like the course of software on a computer. In this respect, the *in vivo* visualizations bear no resemblance to the traditional depictions of development in embryology.

As a science of syntheses and relationships, embryology has been concerned with complexity, integration, and context from the very outset. With the aid of the computer, it is now no longer the aim of research to fix embryos histologically, manipulate them experimentally, and then make their development visible in a series of images, as was the practice for centuries. Instead, research now observes how organ formation advances in numerous steps from a single cell to more complex structures. To this end, a model of development based on experimental data is run on a computer, the complexity of formation increasing with every iteration, as does the amount of experimental data. Becoming more complete and data-saturated with every run and modification, the model is supposed to become increasingly predictive, too. The *in silico* model is thus aimed at serving as a hypothesis of how the process works as a whole, *in vivo*. Working with individual components and their relationships, development is framed as an emergent property whose qualities can be understood not through analysis of the components but through the integration of data from the level of cells to the entire organism and its maternal environment. Edelman et al. (2010) and Khairy and Keller (2011) explain all of this thoroughly.

Conclusion

Making the dynamics of nature visible and the moving image a topic of research changes our view not only of nature as a whole but also of the individual. The modeling of processes is based on large sets of data and follows the rules of mathematical and computational formulization. Experiments, on the other hand, are still conducted on individual organisms and with the aid of individual model organisms. The dynamization of nature in systems biology and scientific animation is thus based on both individual surveys and statistical values. This raises the fundamental question of whether the processes and events that constitute nature have a meaning as singular occurrences or whether future science will redefine the individual as merely an average value within a possible sample space.

LINGUISTIC FRAMEWORKS

Linguistic analysis utilizes linguistic frameworks in a variety of ways. Sometimes referred to as *linguistic methods or linguistic approaches*, linguistic frameworks can be understood as conventions, or sets of rules, that enable discussion and analysis of new entities; in other words, they are forms of language that govern the ways in which these entities are described and referenced.

A linguistic framework is thus a way of organizing human communication about wide sets of experiences or observations. A simple example of such a linguistic system would be a mathematical system, in which a problem is solved by deduction from the axioms of the system.

According to the philosopher Rudolf Carnap (1891–1970), for every linguistic framework, there exist two specific types of questions: internal questions, which are asked and answered within the framework, and external questions asked of

the larger system within which the entities are supposed to exist. Not only did this conception play a central role in logical positivism, but it also greatly influenced the development of the philosophy of science. Both internal and external questions are essential in the building process of *linguistic frameworks*.

Building and Implementation of Linguistic Frameworks

The process of building a linguistic framework can be described as follows. If someone wishes to speak in their language about a new kind of entity, they have to introduce a new system of ways of speaking, subject to new rules. This procedure is called *the construction of a linguistic framework* for the new entities in question. Thereafter, it is necessary to consider whether the entities exist within this framework. This is the internal question. Regarding the external question, it concerns the existence of the entire reality of the system of entities as a whole. Internal questions and answers to them are formulated with the help of the new forms of expressions. The answers may be found by purely logical methods or by empirical methods. This depends on whether the framework is a logical one or a factual one.

The simplest example of entities used in everyday language could be the spatiotemporally ordered system of observable things and events. Once we accept the language with its framework, we can ask empirical questions: *Is there a white paper on the table? Did King Arthur actually live? Are unicorns and centaurs real or imaginary creatures?* These questions need to be answered through empirical investigations. The results are evaluated according to the rules that confirm or refute the evidence for possible answers. For this purpose, explicit rules of evaluation have to be put down in advance.

By contrast, *What are things?* is an external question. The distinction is perhaps even easier to see when the framework in question is that of numbers; clearly *What is 2+2?* is internal and *Are numbers real?* is external. For Carnap, such external questions are not just unanswerable but fundamentally flawed in their formulation. It is

meaningless to ask what is *real* outside the context of the framework because it is the framework that contributes to the cognitive content with which these questions are posed.

Given that natural language emerged as a means of enabling humans to effectively communicate with each other, and not as a means of *finding truth* or any other such modern abstraction, it is reassuring to find a theory that places its emphasis on linguistic convenience rather than on a search for deep metaphysical insights. One might even take a speculative step further to suggest that human minds, primed as they are for linguistic development, are inherently predisposed to accept certain frameworks of exceptional utility (e.g., thing-language) regardless of how flawed or incomplete they might be. It has been suggested that human brains are naturally sensitive to certain grammatical forms and constructions; it is likewise known that even infants have a sense of object persistence and number conservation. Both observations lead one to the idea that thing- and number-language are *natural* frameworks to accept natural ways of organizing our perceptions of the world.

Carnap established the concept of *linguistic frameworks* to cope with the problem of constructing abstract entities within an empiricist frame of reference, and it is not surprising that a major advantage of the idea lies in this area. References to abstractions, particularly those derived from the sciences—coordinates, vectors, and many more—can be freed from implicit Platonism and given their own theoretical grounding as entities introduced by useful and productive linguistic frameworks. This structure offers a clean way of viewing abstractions within an explicitly empiricist worldview.

The linguistic framework thesis is also characterized by a second class of advantages related to traditional ontological problems. One of them is that it does not trip over the nonexistent referent problem; denying the existence of an entity is as simple as stating that the linguistic framework in which the entity is introduced is not productive or expedient.

A related advantage is that the acceptance of linguistic frameworks is fundamentally a pragmatic matter, ultimately adjudicated by *their*

efficiency as instruments. This attitude admits the utility of limited descriptive languages, such as that of Newtonian mechanics, without appealing to the nonsensical concept of *ultimate truth or falsity*.

Instances of Linguistic Frameworks
